The question was then considered whether it were not possible that meningeal hemorrhage was taking place upon the opposite side. The rarity of such a state of affairs, combined with the lack of symptoms pointing conclusively to meningeal hemorrhage, led to the conclusion on Dr. Porter's part that if the patient were to pull through at all, her chances would be as great without as with further operation, a conclusion justified by the autopsy, which revealed no lesion at the surface of either side—in fact, nothing tangible beyond two small hemorrhages in the left frontal region, far removed from the course of the motor fibres.

This case seems to us peculiarly instructive in view of its atypical course. With regard to the question of operative interference the deductions to be drawn, are, of course, purely negative. It emphasizes, however, the importance of remembering that a fatal result may follow severe concussion without tangible gross lesion, unless, indeed, the two small hemorrhages in the frontal lobe with subsequent softening are considered adequate cause for a fatal issue. Whether this be true or not, they were certainly insufficient to produce the paralysis.

The study of this case and the considerations thereby suggested show the complexity of the question from a modern standpoint, compared to the view of former times, when so crude a law obtained as that

unconsciousness of brief duration showed concussion, while protracted unconsciousness pointed to compression; in this case certainly the unconsciousness and death can hardly be attributed to this mechanism. As to the exact cause of the fatal issue we are still unfortunately in doubt.

Assuming that the brain was unable to recover from the general disintegration produced by the mere violence of the blow, we are still confronted by the question, Why should marked unilateral paralysis, including that of the face, be present? Experience certainly would tend to show that the force of so violent a concussion should produce some effect at least upon the opposite side. Great as is the advance in the modern study of cerebral trauma, we are still far from the solution of such pathological problems as these, although a careful study of the subject has led in individual cases to brilliant practical success. Among these cases the one here reported can unfortunately not be counted, but it is offered with the hope of adding something to the sum total of our knowledge of the subject.

It seems not improbable that the diagnosis, *cerebral edema*, will appear more prominently in the future than it has in the past. Attention has been for some time directed to edema as a cause for more or less transient paralysis in non-traumatic cases; and in traumatic cases Dr. Bullard has offered this pathological condition as an explanation of the lack of correspondence between the amount of hemorrhage found in given cases, and the extent of the paralysis. He combats the objection that post-mortem evidence has failed to justify this diagnosis, contending that this fact by no means establishes its absence during life. Our case certainly tends to corroborate this view, for the ante-mortem evidence of increased fluid was demonstrated at the operation, though none was found at the autopsy. That the pressure of this fluid played a part in the production of the hemiplegia can hardly be doubted in view of the disappearance of rigidity, and the improvement in motion following the relief of pressure by operation.

One of the writers, in presenting an argument for the vaso-motor theory of grand hysteria, has called attention to the possibility of localized edema in the brain as productive of so-called functional hemiplegia and monoplegia. We certainly have an analogous process in the peripheral swellings not infrequently found in hysteria, more particularly about the wrist and ankle-joints.

It is not uncommon in children to find localized paralysis following blows upon the head, closely simulating the results of hemorrhage, but completely disappearing in the course of a week or two, a fact which has to be borne in mind in making the diagnosis of middle meningeal or other hemorrhage in early life. The case here reported, together with others which have been called to our attention, would seem to indicate that a similar condition may obtain in adult life. Whether this pathology is accepted or not, the practical bearing of such cases upon our experience is to throw a certain weight in favor of conservatism in doubtful cases, though by no means lessening the demand for operation in the typical case.

It is of the utmost importance that we learn, if possible, to recognize the class under consideration. Towards this result we have only the following suggestions to offer, based upon our own experience. In the

first place, in all of the cases of hemorrhage which we have seen, the unconsciousness, after once appearing, has steadily increased.

The other symptoms have shown, as a rule, steady and continuous progression. The cases simulating hemorrhage, on the other hand, have run a comparatively irregular and atypical course. The insensibility to pain has also been profound in cases of hemorrhage, after reaching the point of unconsciousness. In the cases like the subject of this paper, however, pressure over the hematoma has given rise to signs of discomfort long after the unconsciousness was so profound that no response to questions could be elicited. The so-called pressure pulse has also been absent, though this sign is often wanting in meningeal hemorrhage, probably on account of the laceration, active congestion and other irritative lesions tending to increase the pulse-rate.

Apart from general scientific interest, to the practising surgeon and neurologist the pathological diagnosis of those cases becomes one of sufficient importance to demand discussion. Few more serious questions confront the surgeon than that of operative interference in this class of cases. Notwithstanding the relative innocuousness of trephining, as adduced by some authorities in favor of free exploration in doubtful cases, occasional unhappy results follow this operation, especially if the dura is incised and the brain substance explored. Even were this not the case, the antipathy of the family and friends to opening the cranial cavity presents a serious obstacle, except when the surgeon can promise relief.

The first question to be decided is whether hemorrhage is present. If this question is answered in the affirmative, we have still to consider whether the flow has ceased. If it has not ceased, has enough blood escaped, or is enough blood likely to escape to cause immediate danger, or to result in permanent symptoms? If, on the other hand, the hemorrhage has ceased, will the symptoms disappear on absorption of the clot, or will a cyst be formed which may give rise to future trouble? These questions we do not propose to discuss at this time, having rather to do with cases in which we are not sure that hemorrhage exists.

The points of diagnosis occurring to the writers, apart from the classical symptoms of hemorrhage, have been already mentioned; we would only add here, that when the surgeon thoroughly familiar with the subject feels himself in doubt, the chances are on the whole against hemorrhage, though the case reported by Mr. Hutchinson offers a remarkable exception to this rule. The following is a brief abstract:

Fracture of the right parietal bone, involving base of skull, rupture of middle meningeal artery; death on the ninth day from erysipelas and pyemia.²

The man had fallen head first, with a severe laceration of the scalp over the right parietal bone; exposure of the bone showed no fracture. He was conscious, answered questions, put out his tongue, etc. Was not paralyzed. Six hours later his general condition became worse. Pulse 84, soft and deliberate. Pupils rather small, equal. Left limbs moved much less vigorously than right. Complained when irritated but would not answer questions. Somnolent. Mr.

² Mr. Hutchinson's lectures on "Compression of the Brain," London Hospital Reports, vol. iv, p. 11, et seq; quoted by Jacobson, Guy's Hospital Reports, vol. xliii.

Hutchinson considered the condition, for the most part, severe concussion in the stage of partial recovery from collapse; but he had one symptom which did not fit with mere concussion, that is, partial paralysis of the left arm and leg. Several of the general symptoms of compression, however, were absent.

The man was not insensible, the pulse not impaired, the pupils not dilated, the breathing not stertorous. Mr. Hutchinson suggested the possibility of contusion of the right middle lobe of the brain in addition to concussion, and advised trephining if the paralysis increased and the patient became insensible. On the following day the hemiplegia had disappeared and consciousness returned. The patient had been restless during the night, and had twice got out of bed, but was unable to stand without assistance. Respiration tranquil, pulse 80. Patient was absolutely deaf, a condition which Mr. Hutchinson explained by some central hemorrhage implicating the auditory ganglia. On the third day erysipelas of the scalp appeared and spread to the face; on the sixth day symptoms of pyemia appeared; and the patient died on the ninth day. The only new symptom pointing to middle meningeal hemorrhage was dilatation and immobility of the right pupil.

The autopsy showed fracture of the base, with two lines passing forwards across the petrous bone and meeting in the top of the sphenoid. On both sides the cavity of the tympanum was full of blood-clots, the membrane being unbroken. This explained the absence of bleeding and the complete deafness. On the right side of the skull a fissure passed forwards through the sphenoid and temporal bone into the parietal. By this fracture the middle meningeal artery had been torn, and a large effusion of blood between the bone and dura mater had followed. The clot was an inch thick, and consisted probably of two or three ounces.

It will be noted that Mr. Hutchinson, in explaining paralysis, made the diagnosis *local contusion*. This term, as well as that of *laceration*, is not infrequently used. Post-mortem examination, however, is strikingly negative as regards laceration, except where the brain had been torn up by actual hemorrhage. In our own case, in which a certain degree of laceration was almost taken for granted, the macroscopical examination failed to show any trace of this lesion, either at the operation or at the autopsy. It seems to us more probable that in such cases, local edema, resulting from contusion, is a not unreasonable diagnosis. Dr. Bullard has already called attention to such edema accompanying hemorrhage, but mere bruising might well suffice for its production.

Suppose we have made a diagnosis of local cerebral edema, ought we to operate? If it be determined that such local edema cannot produce paralysis, a negative answer is in order; and even assuming that edema has produced paralysis, is it worth while to remove the fluid, or ought we not rather to wait patiently for its absorption? In considering this question, it seems to us that if the brain injury is so profound that the circulation is unable to re-establish itself and carry off the fluid, the patient is beyond help from operation or other treatment. Our tendency, therefore, in case we were assured that edema was the only lesion, would be to leave the patient alone.

It may be objected that the mere temporary pres-

ence of edema may prove disastrous; but here again we should say, if the patient is so low that temporary local edema will precipitate a fatal issue, he is too low to react from operation. If operation is decided upon, however, and only edema found, the surgeon should not feel that a mistake has been made, for in any such case he could never have been *sure*, without operation, that no hemorrhage existed. In other words, in a case of local paralysis, it can never be a mistake to operate provided the patient is growing worse or has even ceased to improve. In such a case the point of election might seem to be the anterior branch of the middle meningeal artery. Jacobson has, however, called attention to the advisability, in case trephining at this point proves negative, of making another opening in the region of the posterior branch of the same artery. It seemed to us in our case preferable to select a point between the two branches, from which the bone could be removed in either direction by the Rongeur forceps, particularly as the point we selected brought us in the neighborhood of the facial centre, at a place where hemorrhage from the middle cerebral artery (sub-dural) would be likely to show itself, for the symptoms of hemorrhage from this artery are nearly identical, so far as the paralysis is concerned, with those of the hemorrhage of the middle meningeal.

It is desirable that careful reports of similar cases be collected, in order that general rules may be formulated, to aid in the diagnosis of this important and often puzzling variety of trauma.

ARE ESPECIAL HOSPITALS OR HOMES FOR CONSUMPTIVES A SOURCE OF DANGER TO THEIR NEIGHBORHOOD?

BY EDWARD O. OTIS, M.D., BOSTON.

ALL authorities agree that consumption or pulmonary tuberculosis is infectious or communicable only through the dried sputum. When this becomes de-livered the infecting micro-organism, the tubercle bacillus, is set free in the air and enters the respiratory tract through inhalation. The larger the air space and the more frequently and constantly this changes, the less likelihood is there that any given portion of this space will contain the germs although they may be present somewhere in the given area; hence the chance of becoming infected out of doors is exceedingly small in comparison with the danger in a confined space, like a room occupied by a consumptive or any enclosed space where there are likely to be one or more consumptives and where the sputum is not safely disposed of. Further, air and light—the condition out of doors—are inimical to the life of the tubercle bacillus. Ransome and Professor Delépine communicated to the Royal Society of England in May, 1894,¹ the results of their experiments “to determine how short a period of exposure to air and light would suffice to destroy the virulent action of the microbe.” They found that all specimens of dried sputum exposed to both air and light even for two days only, and for one hour of sunshine, had entirely lost their power for evil.

In concluding his remarks on these experiments Dr. Ransome says, “that where tuberculous sputum

¹ Published in Vol. lvi of the Proceedings; quoted in “The Treatment of Phthisis,” by Arthur Ransome, 1896.

can be exposed to sufficient light and air to deprive it of virulence before it can be dried up and powdered into dust, no danger of infection need be dreaded. It is only when there is sufficient organic material in the air, derived from impure ground air, or from the reek of human bodies, that the tubercle bacillus can retain its existence and its virulent power. Long-lived though it may be under these conditions, it is rapidly disinfected by the natural agency of fresh air and sunlight; so rapidly that where these agents are present, even in comparatively moderate degree, the tuberculous material cannot reach its dangerous state of dust before it is deprived of virulence." Dr. Irwin H. Hance in his paper upon the infectiousness of the dust in the Adirondack Cottage Sanitarium,² also says, "The most powerful and at the same time freely obtainable agents are the sun's rays and diffused daylight. They can be used by everybody, and have been proved to be the most efficient disinfectants known."

From the above, then, it is a fair inference, that, wherever there is a community of consumptives, either in hospital or at large, in the midst of a town or surrounded by numerous dwellings, if there is an abundance of air, light and sunshine, the danger from infection is exceedingly small, even though no adequate means is employed to destroy or disinfect the sputum. Whereas, I believe there is more or less danger from infection in open resorts—that is, where patients live about in boarding-houses, hotels and the like, not in consumptive hospitals or sanitariums—I believe the danger for the most part arises from the indoor sources of infection, not from sputum scattered out of doors. The inhabitants of these places are brought into intimate contact with the consumptives as servants, attendants, etc., and thus contract the disease from those they serve who are under no such control and supervision as are those in a sanitarium.

On this point, however, others of large experience differ from me, and do not think there is much of any danger, as the following shows: In Colorado Springs, where there is said to be more cases of pulmonary consumption in proportion to its population than any other city or town in the United States and perhaps in the world, Dr. S. E. Solly, a well-known writer and authority on consumption and climatology, says, in a communication to Dr. Clinton Wagner of New York: "The dangers of contagion from a consumptive are so easily controlled that it is by no means necessary to separate consumptives from healthy persons. You ask me concerning my experience here. At least a third of our population are consumptives. The town which contains some 15,000 people, has been established twenty years. An inquiry made by disinterested physicians into the number of cases of consumption that were known to have originated in the town resulted in a report of 20 in all. Although it is probable that our brilliant sunshine and dry air more quickly destroys the vitality of the bacilli than your eastern atmosphere, yet in the poorer lodging-houses of the town there are many ill-ventilated rooms, inside or on the north side of the building, inhabited by consumptives and their families, where recklessness of expectoration and carelessness of ordinary cleanliness are marked features of their domestic *ménage*; yet cases of contagion do not average more than one a year."

² Medical Record, New York, December 28, 1895.

Of Davos Platz, in Switzerland, where also large numbers of consumptives congregate, Dr. Clinton Wagner says:³ "At Davos Platz, in Switzerland, where I spent a winter a few years ago, a very large number of consumptives were staying. The hotels were crowded, and of the 1,500 strangers in the village, above 1,000 were consumptives. At the hotel at which I stayed there were about 120 guests, about 80 of whom were consumptives. At Davos, during the winter, the invalid's day for outing is limited to four and one-half hours, the remainder of the twenty-four hours is spent within doors. No one stood in dread of contracting the disease, and no case occurred in which it was conveyed from person to person. No special precautions were taken by the physicians and local authorities to prevent contagion, other than good ventilation of the living- and bed-rooms. As at Colorado Springs, no cases of the disease originated at Davos."

In health-resorts where the so-called closed treatment of consumptives is carried on in sanitariums, we have evidence that there is no danger of infection to the inhabitants of these resorts; whatever may be the case in the so-called open resorts. At Göbersdorf and Falkenstein, in Germany, are two of the oldest and largest sanitariums. The former has been visited by 25,000 patients during forty years, and the mortality from consumption among the inhabitants has never passed the average, but on the contrary has diminished.⁴ During the period of twenty years preceding the establishment of the Falkenstein Sanatorium an average of four per cent. of the inhabitants died annually of consumption, and 18.9 per cent. of the total mortality was attributed to that disease. After the institution was opened, during the period from 1877 to 1894, the average annual mortality from consumption fell to 2.4 per cent., and the proportion of deaths from consumption to those from other causes sank to 11.9 per cent.⁵

Says Dr. V. Y. Bowditch, of Boston, in a paper presented at a meeting of the American Climatological Association, at Lakewood in May, 1896: "I wish to refute the statements that properly regulated consumptives' hospitals are sources of danger to the community, when I believe them to be exactly the opposite as shown by statistics." Says Knopf:⁶ "Well-conducted sanitariums for consumptives are not centres of infection; but, on the contrary, places where the tuberculous patient is the most free from the danger of auto-infection, and where there is the least chance of his communicating his malady to others."

There are already existing in thickly-settled centres many hospitals either exclusively for consumptives or which contain large numbers of them: the great consumptive hospital of Brompton,⁷ Victoria Park, Royal Hospital for Diseases of the Lungs, North London Hospital for Consumptives, in London; the Royal National Hospital for Consumptives, in Ventnor, Isle of Wight, a favorite and much frequented seaside resort; the Manchester and Liverpool (Eng-

⁵ Quoted in the New York Medical Journal, February 22, 1896.

⁶ Are Sanatoriums for Consumptives a Danger to the Neighborhood? by S. A. Knopf, M.D. (Paris and Bellevue, N. Y.), formerly Assistant to Professor Dettweiler, Falkenstein Sanatorium, Germany.

⁷ This hospital is situated in the midst of a dense population in London, where the mortality from phthisis is no greater than anywhere else in the city. Knopf, "Les Sanatoria de Phthisiques, Sont-ils un Danger?" "Revue de Tuberculose," Vol. iii, 1895, p. 317.

land) Hospital for Consumptives; St. Joseph's Hospital (300 beds); Dispensary for Consumptives and Others, in New York City; the Rush Hospital for Consumptives and Allied Diseases, in Philadelphia; a small, charitable hospital for consumptives in Baltimore. In Germany a number of special hospitals for consumptives have recently been established or proposed at Bremen, Breslau, Dresden, Hanover, Cologne, Frankfort-on-the-Main, Worms, Stettin, and two in Berlin.

It is fair to presume that if such hospitals were a menace to the neighborhood they would hardly be permitted to be established or remain. How many of the general city hospitals have constantly numbers of consumptives in their wards: at the Carney Hospital, South Boston, for example, there is always a large contingent of them.⁸

As to the danger of infection in consumptive hospitals or homes *themselves* we have abundant evidence. Dr. C. T. Williams, physician of the Brompton Hospital for Consumptives in London (containing 231 beds), says⁹ that statistics of forty years of the Brompton Hospital and also those of Victoria Park Hospital (consumptive) directly negatives the idea of infection either to the resident staff or to patients admitted to the wards for other diseases than consumption. "It is obvious therefore," he says, "that phthisis is not contagious in the same sense as scarlatina, small-pox or other acute fevers."

Dr. Irwin H. Hance, assistant to Dr. Trudeau at the Adirondack Cottage Sanitarium, in "A Study of the Infectiousness of the Dust in the Adirondack Cottage Sanitarium,"¹⁰ proved by the inoculation of guinea-pigs (an animal much more susceptible to tuberculosis than man) that 16 out of 17 cottages inhabited by consumptives for so long a period as ten years, were absolutely free from infectious material. In the exceptional cottage (the 17th) the patient had disobeyed instructions and expectorated wherever convenient. Dr. Hance further says that "added clinical proof of the non-infectious character of the dust may be deduced from the fact that not one of the twenty to twenty-five attendants has ever developed tuberculosis; and also that no patient who was admitted suffering from pulmonary disease without the bacilli being present ever subsequently developed them."

Dr. G. A. Heron¹¹ inoculated 100 guinea-pigs with dust taken from various sources in the City of London Hospital for Diseases of the Chest; 26 died of acute inflammation spreading from the site of inoculation. Of the remaining 74, two pigs died of tuberculosis; the dust in each case came from the tower of the hospital which acts as up-cast shaft, and was damp and unventilated.

In "A Further Study of Tuberculous Infection of Dust" by Dr. Hance,¹² he took dust from various tenement-houses where there were consumptives, two hospitals (Bellevue and Charity), and from several street-cars. In the tenement-houses where the family had paid attention to the instructions and regulations given them by the Board of Health, none of the

guinea-pigs inoculated with the dust were affected with tuberculosis, while in the dirtier tenements, two out of three were found infected. In the cars one out of five was found dangerous. In the two hospitals, no case of tuberculosis developed in the animals from the dust with which they were inoculated. Dr. Hance also took the dust from the waiting-room of the Out-patient Department of Bellevue Hospital, and found it infected with tubercle bacilli. In the "Winah" Sanatorium for Consumptives at Asheville, experiments with the dust gave likewise negative results.

Cornet, a well-known German investigator, collected dust from rooms occupied by consumptives, and inoculated 311 animals. One-fifth of the whole number were found tuberculous, but in no case was the dust of the walls infectious when sputum cups were used exclusively to receive the expectorated matter.

The above cases, I think, are sufficient to prove conclusively that in a sanitarium or hospital for consumptives where the sputum is properly disposed of there is no danger of infection either to those within or without them, and moreover that it is possible to properly dispose of the sputum.

With regard to the more infectious diseases of diphtheria, scarlet fever and measles, there is probably less danger from them even than the public supposes, as the following statement from Dr. John S. Billings, late Deputy Surgeon-General of the United States Army, and well-known in this country and abroad as an authority upon hygiene, shows: "It is above all things desirable," he says, "to get the public to understand that there is very little danger in a hospital for diphtheria, scarlet fever or measles, separated the width of an ordinary street, even, from the surrounding houses. If there was a hospital of that kind next door to my house, separated by a brick partition wall, I should not have the least fear of anything coming through it or of any contagion coming from it."¹³

VERATRUM VIRIDE IN PUERPERAL CONVULSIONS.

BY WM. HENRY THAYER, M.D., BERKSHIRE, MASS.

In the treatment of puerperal convulsions — while recognizing uremia as the constant predisposing cause, which may become the exciting cause — we must, of course, consider that the exciting cause may be reflex, requiring evacuation of the uterus, the stomach or the bowels, for their arrest. All practicable measures to that end having been taken, as by active cathartics or emetics, as indicated, we at once address ourselves to the nerve centres, to control nervous excitability until the exciting agent can be eliminated.

For this object, venesection was the reliance until the employment of ether by inhalation largely superseded it. If venesection sometimes failed to relieve, ether never did, while the patient was kept unconscious; and it could safely be continued until delivery or free catharsis occurred, which usually terminated the paroxysms. It has been found, however, that *veratrum viride* in large doses will act as thoroughly as ether; and its effects can be continued, and without producing unconsciousness.

In the condition of the nervous system that exists in puerperal convulsions, there is a peculiar tolerance

⁸ I am informed by the sister in charge that there are never less than thirty, and that the few of those who are able to leave the wards enjoy fresh air on the grounds of the hospital and occasionally on the "heights." There has been no complaint from the neighborhood in regard to this class of patients.

of veratrum viride, so that the officinal dose has no effect. But large doses quiet the nervous erethism, producing a decided effect in a short time — sometimes in fifteen minutes, but almost certainly within an hour — and keeping the nervous system under control for several hours. The administration is followed by cooling of the surface, great lowering of the pulse in rate but not in strength, and along with this complete arrest of the convulsions. The state of the pulse is the guide in treatment. From a high rate, which rules in the disease, it is reduced to the normal standard or below it; and while it is kept below 60 there need be no fear of a recurrence of the paroxysms. When this effect has been once produced, it will continue several hours, and a single dose will do it; if not apparent within an hour or less, the medicine must be repeated in smaller doses; and it can be safely repeated at intervals until the pulse begins to fall. With the pulse for a guide, no untoward symptoms need occur from its use; the pulse may be brought down to 50, without any general depression; if carried so far as to produce vomiting, we may find great prostration produced by the nausea, which is overcome within thirty or forty minutes by opium, or any diffusible stimulant — perhaps in less time by a solution of morphia hypodermically.

Dr. Norwood, of South Carolina, who introduced the use of veratrum viride as a very efficient agent in the treatment of acute febrile and inflammatory diseases, calls it "an arterial controller or vascular regulator," and says, "its primary effect is to render the pulse slow, full, distinct and stronger. . . . It allays morbid irritability in the nerves and muscles of voluntary motion. . . . We have found nothing that arrests convulsions in children, accompanied with high febrile symptoms, with anything approximating such certainty and speed. . . . Why would it not be the remedy in puerperal convulsions, when accompanied with frequent pulse, great heat and dryness of the skin, alone, or after blood-letting, where venesection was indicated?"

But Dr. Norwood never tried it in puerperal convulsions. In the paper from which I have quoted, published in 1868, he says, "In puerperal convulsions there is no remedy equal to stramonium."

The employment of veratrum viride in large doses in puerperal convulsions was first reported to the King's County Medical Society (New York) by Dr. Herbert Fearn, of Brooklyn, in 1869, substantiated by cases in which he had used drachm doses of the tincture, sometimes required to be many times repeated, with favorable results. This paper was published in the *American Journal of Obstetrics*, etc., May, 1871. I subsequently reported to the Society the following case, which will be sufficient for an illustration.

I was sent for at 9 A. M. to see a patient in consultation. She was a primipara, age twenty-five, two years married; had had one miscarriage; was now at full term. Had had no trouble during her gestation; very moderate edema of lower extremities for several weeks; nothing was known of her urine; her bowels had been evacuated daily. The day before, she was to all appearances well, but in the evening had an attack of indigestion. Her physician was summoned at 10 P. M.; found her vomiting and complaining of cramp in the stomach; gave her ipecac, and afterwards cathartic doses of calomel. She became relieved; but at 4 A. M. had a convulsion, and had had no defecation.

The convulsions continued at intervals of half an hour or more till 9 A. M. They were severe and protracted, with frothing at the mouth, lividity of the face and total unconsciousness, followed by coma and stertorous breathing; then an interval of partial restoration, but with indistinct utterance and without any recognition of friends. Between 4 and 9 o'clock she had been treated with tartrate of antimony in emetic doses; several asafetida enemata, which had operated on her bowels; had been bled four ounces; and had had powerful sinapisms on various parts of her body. When the coma passed off, she was very restless, throwing herself about and talking indistinctly and incoherently. Her pupils were dilated; pulse 120, hard, but not excessively full. The os uteri was high up, slightly dilated, the cervix not entirely obliterated, and a uterine contraction took place during the examination.

Her physician readily acceded to my proposal to give veratrum viride in full doses, and at 9.40 A. M. we gave her nearly one drachm of the tincture. At 10 A. M. a convulsion as severe as before; at 11, another convulsion, and the last. As soon as she aroused from this she took twenty-five drops of Squibb's fluid extract of veratrum viride, which had been sent for on suspicion that the tincture we had administered was not of standard strength. But the relief probably came from the first dose, for she vomited almost immediately after swallowing the fluid extract, and probably rejected all of it. The vomiting continued for an hour, with great restlessness, the patient throwing herself almost incessantly over to the left. At 12.15 P. M. I saw her; found her rational, and inclined to sleep, saying that her head was nearly free from pain; her pulse was 60 and soft. Labor went on well, and she was delivered of a dead child at 2.30 P. M. At 5 P. M. I found her quiet and comfortable, with a pulse of 84.

Since 1869, when Dr. Fearn's paper was read, the treatment of puerperal convulsions with veratrum viride has been slowly gaining favor; of which we have evidence in many communications to various societies and medical journals. Bartholow, in his "Materia Medica and Therapeutics" (1888), says: "Dr. Sullivan, of San Francisco, informs me that veratrum viride (half a drachm of the fluid extract every fifteen minutes, until nausea or vomiting ensues) is invaluable in puerperal convulsions. Barker, in his 'Puerperal Diseases,' had already called attention to its utility; and Boyd confirms the previous observations. Increasing experience adds to the testimony regarding its exceptional value in relief of this formidable malady."

The experience of one general practitioner in puerperal convulsions is not very great; but in the convulsions of children, I have regularly employed veratrum viride for twenty years past with excellent effect; and as a prophylactic in ephemerical fever in children who are subject to convulsions.

I believe the use of veratrum viride in puerperal convulsions originated in Brooklyn, where its value is now generally recognized. It has gained ground elsewhere, as rapidly as could be expected of the management of an affection so infrequent, and promises in time to supersede all other methods of treatment.

In Chicago every dealer in cigarettes must pay an annual license of one hundred dollars.

Medical Progress.

REPORT ON PROGRESS IN PUBLIC HYGIENE.

BY SAMUEL W. ABBOTT, M.D., BOSTON.

WHAT IS A NUISANCE?

A LEGAL definition of a sanitary nuisance is occasionally sought for, and the following comprehensive definitions may serve as an answer to the question. They are quoted from the Public Health Act of Scotland, Section 16.

"(a) Any insufficiency of size, defect of structure, defect of ventilation, want of repair, or proper drainage, or suitable water-closet, or privy accommodation, or cesspool, and any other matter or circumstance rendering any inhabited house, building, premises, or part thereof injurious to the health of the inmates or unfit for human habitation or use.

"(b) Any pool, water-course, ditch, gutter, drain, sewer, privy, urinal, cesspool or ashpit, so foul as to be injurious to health, or any well or other water-supply used as a beverage, or in the preparation of human food, the nature of which is so tainted with impurities or otherwise unwholesome as to be injurious to the health of persons using it, or calculated to promote or aggravate epidemic disease.

"(c) Any stable (byre), pigstye, or other building, in which any animal or animals are kept in such a manner as to be injurious to the health.

"(d) Any accumulation or deposit of manure or other offensive matter within fifty yards of any dwelling-house within the limits of any town, or wherever situated, if injurious to health, or any accumulation of police manure within a quarter of a mile of the municipal boundaries of any city (except the City of Glasgow), or any accumulation of deposits from ashpits or manure from town or village laid nearer than fifty yards to a public road or dwelling-house.

"(e) Any work, manufactory, trade, or business injurious to the health of the neighborhood, or so conducted as to be offensive or injurious to health, or any collection of bones or rags injurious to health.

"(f) Any house, or part of a house so overcrowded as to be dangerous or injurious to the health of the inmates.

"(g) Any factory, workshop, or workplace, not under the operation of any general act, for the regulation of factories or bakehouses, and not kept in a cleanly state, or not ventilated in such a manner as to render harmless, as far as practicable, any gases, vapors, dust, or other impurities, generated in the course of the work carried on therein, and injurious or dangerous to the health of persons employed therein, or any such factory, workshop, or workplace, as is so overcrowded, while work is carried on therein, as to be dangerous or injurious to the health of those employed therein.

"(h) Any fireplace or furnace which does not as far as practicable consume the smoke arising from the combustible matter used in such fire-place or furnace, and is used within any town, for working engines by steam, or in any mill, factory, dye-house, brewery, bakehouse, or gas-works, or in any manufactory or trade process whatsoever.

"(i) Any chimney (not being the chimney of a private dwelling-house) sending forth smoke so as to be injurious to health.

"Provided that in places where, at the time of the

passing of this act no enactment is in force compelling fireplaces or furnaces to consume their own smoke, the foregoing enactment as to fireplaces and furnaces consuming their own smoke shall not come into operation until the expiration of one year from the date of the passing of this act.

"(j) Any churchyard, cemetery, or place of sepulture so situated or so crowded with bodies or otherwise so conducted as to be offensive or injurious to health."

THE VALUE OF FORMALIN (FORMIC ALDEHYDE) AS A DISINFECTANT.¹

"On the issue of the account of formalin in 1893 it seemed as if an ideal disinfectant had been discovered. Formalin was stated to be a forty-per-cent. solution of formic aldehyde, a product of the oxidation of methyl-alcohol, obtained by passing vapors of this substance mixed with air over a glowing spiral of platinum wire. Under these circumstances a colorless gas is generated, having a pungent odor. It is readily soluble in water, and has a strong tendency when exposed to the air to oxidize into formic acid. Its disinfecting properties are, in fact, due to this reaction. According to the investigations of Löw, Aronsohn, Trillet, and Berlioz, the forty-per-cent. aqueous solution of formic aldehyde possesses the following properties:

"(1) Very great bactericidal powers, even in highly dilute solutions.

"(2) Very moderate toxic action.

"(3) Chemical effect of rendering inert the products of putrefaction — ammonia, sulphuretted hydrogen, etc.

"(4) Its solution, in the form employed, is devoid of injurious action upon the skin and upon all other substances with which it may come in contact.

"(5) It is capable of being used as a solid, a liquid or a vapor.

"(6) In a concentrated state it has a peculiar action upon animal tissues, which has been termed 'leather-forming.'

"(7) It is very volatile, which enables it to be rapidly expelled when it has attained its object.

The author quotes the previous investigations of various writers who have dealt with the properties of this disinfectant, and gives the results of his own experiments, which are set forth in a series of tables. Esmarch-tubes were employed, of nutritive gelatine, to which were added solutions of various degrees of strength, containing from two per cent. to 1 per 100,000 parts of formalin. Fresh bouillon cultures of the bacilli of anthrax, cholera, typhoid-fever, and other spores were introduced into the tubes, and the results, after due cultivation, were ascertained at the end of eight days. The solution of 1 per 10,000 parts in strength was fatal in every case, while all the spores retained their vitality when the dilution was 1 per 20,000. The formalin was also tested in the gaseous state. The disinfectant was likewise used practically upon various materials and with results which are tabulated.

The author sums up the conclusions at which he arrived, which were extremely favorable to this compound, and states that formalin furnishes an excellent and readily-employed disinfectant, capable of being used for a variety of purposes. It not only supplies a want in medical practice, but it is well adapted for domestic uses, and will be most valuable in the army.

¹ Dr. K. Walter: Zeitschrift für Hygiene, 1896, vol. xxi, p. 421.

It can be substituted for the steam jet, and surpasses steam in the rapidity of its action. In all cases where steam cannot be employed, as for instance in the disinfection of dwelling-rooms, or of uniforms, formalin may supply its place with complete success.

The results of Dr. Walter's investigations are briefly as follows:

(1) Formalin in the strength of 1 to 10,000 arrests the growth of the germs of anthrax, cholera, typhoid fever, diphtheria and staphylococcus pyogenes aureus.

(2) In the gaseous form it arrests growth, even when greatly diluted.

(3) In one-per-cent. solutions it kills pure cultures of pathogenic germs in an hour. In diluted alcoholic solutions the effect is more intense.

(4) In three-per-cent. solutions, especially with the addition of alcohol, the hands may be freed from all germs. More extended investigations are necessary to show the degree to which the skin is affected.

(5) By spraying artificially infected matter with formalin solution, and afterward enclosing it in air-tight vessels, such matter may be sterilized.

(6) By means of formalin (or in other words formaldehyde) leather articles, uniforms, etc., may be thoroughly disinfected in large quantities, and without in any way injuring these articles. Twenty-four hours' exposure are requisite for such disinfection. The possibility of disinfecting rooms may be considered as demonstrated by other experts.

(7) Feces are almost instantly deodorized by a one-per-cent. solution, and are disinfected (germ free) in ten minutes by a ten-per-cent. solution.

(8) Formalin acts as well as a caustic.

(9) It is an excellent preservative.

In the following table the author compares the results obtained by the use of formalin, with those published by Koch and Jäger for other disinfectants.

DISINFECTANT.	STRENGTH.	OBJECTS SUBMITTED TO EXPERIMENTS.	TIME REQUIRED FOR DESTRUCTION.
Hydrarg. bichlorid.	1 to 20,000 1 to 1,000	Anthrax spores. Anthrax spores.	10 minutes. 1 minute.
Silver nitrate	1 to 12,000 1 to 4,000 1 to 2,500	Anthrax spores. Cholera and typhoid. Diphtheria.	70 hours. 2 hours. 2 hours.
Acid hydrochloric	2 to 100	Anthrax spores.	10 days.
Acid sulph.	2 to 100 15 to 100	Anthrax spores. Anthrax spores.	53 days. 8 days.
Ferrum chlorat.	5 to 100	Anthrax spores.	6 days.
Calcium chloride	5 to 100	Anthrax spores.	5 days.
Potass. permanganate	5 to 100	Anthrax spores.	1 day.
Caustic lime	0.0246 to 100 0.0074 to 100	Cholera. Typhoid.	6 hours. 6 hours.
Acid carbolie	3 to 1,000 10 to 100	Staphylococcus and streptococcus pyog. Anthrax spores.	8-11 seconds. 24 hours.
Lysol	1 to 100	Anthrax spores.	5 minutes.
Formalin.	1 to 100 3 to 100	Nearly all pathogenic germs. Anthrax spores. All other pathogenic germs.	Less than 30 minutes. 15 minutes. 1 minute.

(Report on Progress in Public Hygiene to be continued.)

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

J. G. MUMFORD, M.D., SECRETARY.

REGULAR Meeting, Monday, December 28, 1896.
DR. C. J. BLAKE in the chair.

DR. G. L. WALTON and DR. W. A. BROOKS presented a paper on

OBSERVATIONS ON BRAIN SURGERY, SUGGESTED BY A CASE OF MULTIPLE CEREBRAL HEMORRHAGE.¹

DR. WRIGHT: You have heard the pathological report on this case. In connection with this autopsy I think it would be interesting to show some of the lesions as they existed in this case. As the report states, there were two good-sized areas of hemorrhagic softening in the left hemisphere, and one beneath the

floor of the right ventricle which was much smaller in size. The condition was one essentially of multiple traumatic cerebral hemorrhage and softening, the softening, arising, of course, from the rupture of a vessel and the consequent necrosis and breaking down of brain substance associated with that condition. I have here two slides showing two of the most considerable lesions. These slides show the brain substance immediately around the two large areas of hemorrhagic softening. They are especially of interest as showing the usefulness of Dr. F. B. Mallory's new method of staining the neuroglia of the brain and they also bring out very clearly a slender zone of necrosis around the hemorrhagic areas.

DR. BULLARD: I have been extremely interested in this paper because it deals with a subject to which I have for some years given attention. A year or two ago I read a paper before this Society stating that increased intracranial pressure followed injury, and since then I have become more and more convinced that such is the case in, at any rate, a considerable

¹ See page 301 of the Journal.

number of cases. Since that paper was printed I have had the opportunity of seeing a number of other cases in which, after trauma, the operation of trephining was performed and in almost every case we found the intradural pressure increased and in almost all cases the patient was very much relieved, at least temporarily, by the cutting of the dura and the relief of pressure.

In regard to paralysis as caused by edema of the brain, I should like to mention a case which I saw with Dr. Lovett in which the patient was found unconscious in his room with a left-sided hemiplegia. I diagnosed cerebral hemorrhage; the patient died within a few hours and the autopsy showed edema of the brain. The limbs on the other side of the body were not affected.

Several months ago a child was admitted to the service of Dr. Watson at the City Hospital who had received an injury to the head and in whom there was a hemiplegia, I believe also on the left side. The symptoms were typical of meningeal hemorrhage. The patient was operated on at my suggestion by Dr. Blake, with the result of absolutely no evidence of hemorrhage. The dura, however, was opened; the fluid underneath, which was considerable in quantity, was evacuated, and the patient, who had been in a very serious condition and seemed unlikely to live more than a few hours, gradually recovered, and within a few days was practically well. I think the first case illustrates the fact that in edema we may have localized paralysis.

The second case illustrates the fact that in certain cases with very serious symptoms, symptoms resembling those of hemorrhage with paralysis, the mere opening of the dura relieves the patient very greatly. In this case I do not think that there was any question but that it saved the patient from, at any rate, a very long unconsciousness and probably saved his life.

In regard to the special case before us, I firmly believe in operating on such cases. I do not believe in the present state of our knowledge we can always discriminate these cases from those of middle meningeal hemorrhage. I do not think convulsions always occur in middle meningeal hemorrhage and I think very often we have no means by which we can determine whether a patient has middle meningeal hemorrhage or a condition like that presented by the patient in this paper. I have seen several cases in which the lesion seems to have been essentially similar to that of the patient here, in which the symptoms could not be distinguished from hemorrhage. I think, even if hemorrhage is not found, much good can be done to the patient by opening the dura. I should, however, instead of stitching it up leave it open. It seems to me that is a very important point. I should also suggest in those cases that the trephine hole be large enough to relieve pressure. We have not found in making large holes and in not suturing the dura that there was any especial danger so long as the wound was kept aseptic.

In regard to trephining both sides when hemorrhage is not found on the side first trephined, it seems to me that in adults this may be often safe; in children it is a more or less dangerous procedure. I have seen children die, I feel sure, from the shock of trephining on both sides. Dr. Hutchinson's case is an interesting one; but I think at the present time we should

feel that any physician who allowed such a case to enter his hospital without a thorough examination of the ears had been somewhat neglectful.

DR. BEACH: I would like to know when the temperature first rose to 102°. Do I understand it was within a day or two after the injury?

DR. BROOKS: One A. M., the next morning.

DR. BEACH: My feeling is that where the temperature rises there must be some septic cause for it, but in cases where the change occurs so soon after injury there is hardly the opportunity for an infection to have taken place; my own experience is that where the temperature rises soon after the injury the prognosis is a most unfavorable one. If it rises early, even if it goes down again, it is very apt to rise again later and go on to a most unfavorable end. Mr. Hutchinson's case seems a fairly clear one of septic infection, erysipelas and pyemia. An interesting case that entered the hospital this year was that of a child seen by Dr. Brooks, who had a compound fracture of the parietal bone about midway between the frontal and occipital bone, a little to one side of the median line. The child did perfectly well a while and then developed a temperature and later convulsions. There was moderate hernia cerebri. Suspecting either edema or abscess as the cause I punctured the brain with a narrow knife and carried it nearly to the floor of the skull in the direction of the right lateral ventricle before a few drachms of thin semipurulent fluid escaped. On culture this fluid was sterile. The child was very weak, in a miserable condition after the operation and it seemed as if it were hardly possible for it to rally. The convulsions ceased and the next morning the temperature dropped between two and a half and three degrees. For a few days the child was markedly better and then had a recurrence of the same symptoms, relieved by entering a silver canula and retaining it in place. Convulsions afterwards recurred. To test the question of the possibility of infection through the ear in another case with fatal result, I had some cultures made where there was some slight discharge from a fissure through the roof of the tympanum. The streptococcus and staphylococcus were both found in the external meatus by Dr. J. H. Wright. The ear was afterwards very carefully made aseptic.

DR. A. T. CABOT said, that, in considering the question of edema and the effect that it could produce on the brain and in the causation of symptoms, he thought that any one remembering the condition of a leg which has suffered from trauma, sometimes almost bursting its skin and requiring extensive leeching or incision to relieve the tension, would realize that a similar condition of a part encased in the bony cavity of the head might produce very great interference with function of the brain. It seemed to him that Dr. Bullard's suggestion was of importance and that in operating upon such a case the drainage should be kept up in order to permanently relieve the intracranial pressure.

He thought it was very difficult to have a rule in regard to the question of trephining after such an injury as Dr. Brooks described. While a paralysis affecting both sides soon after an injury, even if slight in amount, leads to a strong presumption of the generalization of the injury and is usually symptomatic of several scattered injuries in the brain due to the concussion, still, when symptoms are much more marked on one side showing that at one part the in-

jury is probably greater than elsewhere, an operation would seem to be called for, and, even when no hemorrhage is found, the relief of pressure in such cases may be of distinct service.

DR. BEACH: I would like to add that Phelps, of New York, has made a very careful study of 124 cases of serious skull injuries. He found that cases where the temperature reached 105° were invariably fatal.

DR. PRINCE: I think the interest of this case largely centres in the diagnosis; and it seems to me the theory propounded by Dr. Bullard is an exceedingly probable one and correctly represents the facts in a certain proportion of cases. As the subject is so important, I may be permitted to cite a case which probably belongs to this category. I was asked very lately by Dr. Munro to see a small child that was brought to the City Hospital. The history was a perfectly typical one of meningeal hemorrhage. There was a period of consciousness followed by gradually lapsing unconsciousness and paralysis. When I saw the child there was absolute paralysis of the right side; still from certain signs I saw,—the child was not absolutely comatose, and might be roused,—I was inclined to wait and, I must confess with a feeling of responsibility, I advised against operation notwithstanding the symptoms were typical of meningeal hemorrhage. To my joy the next morning every sign of paralysis disappeared and the child was as bright as a button. Of course, one cannot prove that it was edema, but that seems the most plausible explanation. In the particular case reported to-night by the reader, it seems to me there is another condition of affairs that may have been present, a condition to which very little attention is paid in the text-books and which is very infrequently thought of at the bedside; that is the condition of acute hydrocephalus or serous meningitis described by Quincke.

This affection was brought to my attention the other day in a practical way and I am inclined to think it is a very important one. Quincke some time ago in a monograph called attention to acute hydrocephalus or serous meningitis as a cause of a condition similar to that presented here. It may occur in the acute form, or subacute, or chronic, and may occur after trauma. The general symptoms are those of severe brain trouble; that is, vomiting, headache; with or without fever as the case may be, but optic neuritis is apt to be present, and coma and delirium. In other words, general symptoms of cerebral disease. But there is one peculiarity in the symptomatology which is quite striking and the presence of which in the case just reported impressed me as the paper was being read before I heard the diagnosis, and that is the variability in the intensity of the symptoms; the patient being apparently better one day and worse the next, one day one symptom being most intense, another day, another; that seems to be a marked peculiarity of this condition. There is a chronic form in which the symptoms resemble those of tumor, and Quincke claims another form that resembles neurasthenia. The fact that it occurs seems to be pretty well recognized now, theoretically, though it is rarely considered at the bedside. Looking back I can see a few cases met with in the past in which the diagnosis was uncertain but which now I am inclined to regard as serous meningitis. As an example I will mention the following case admitted to the City Hospital in the service of Dr. Munro. A young woman knocked

down by her husband and kicked about the head. Her head was very much bruised when she came to the hospital and she was in a bad condition. Without attempting to give the details of the case, I will say that after the first few days the general symptoms of head injury (headache, vomiting, delirium), passed away and she followed a course of ups and downs, at one time showing few symptoms, at other times one or more being obtrusive. Finally, paralysis of the cerebral nerves appeared and I made the diagnosis of cerebral abscess with probably purulent meningitis following rupture of the abscess. I advised an exploratory operation. The operation was performed by Dr. Munro and no abscess was found. At the autopsy nothing but acute hydrocephalus was found. It seems to me in the case reported to-night there were certain symptoms suggestive of this condition. But, Dr. Wright tells me there was no marked amount of fluid found in the ventricles. It is possible the fluid may have been drained by the operation. If so, I must admit it is a point against this diagnosis for if the fluid was drained by the operation, it would seem as if the acute hydrocephalus ought to have been relieved. But this same point would tell against edema, and what is sauce for one diagnosis is sauce for the other; at any rate the question of serous meningitis must be taken into consideration in such cases.

DR. P. C. KNAPP: I would like to endorse what has just been said to us with reference to the advisability of lumbar puncture in those cases where there is doubt as to the diagnosis. Quincke in a recent paper supplementary to his monograph has reported an autopsy of one case where there was in addition to the internal hydrocephalus a very considerable effusion into the pia, an edematous condition of the pia, and in several other cases of which he gives the clinical report there was distinct relief obtained by lumbar puncture. I would endorse what Dr. Bullard has said with reference to the importance of these edematous conditions in traumatic cases. I am a little surprised at the statement which has been made with reference to the differential diagnosis, because certainly in a considerable number of the cases of meningeal hemorrhage that I have seen there have not been at any time any convulsions. Even in one of the last cases I have seen there was not the condition of steadily increasing coma; on the contrary, the patient was partially conscious and the condition seemed to vary from day to day. He was so far conscious that he would look about. There was no paralysis, and at his wife's request he would protrude his tongue, though neither Dr. Watson nor I could induce him to do so. In that case we found a considerable hemorrhage, so that I think we cannot be absolutely certain from either of those diagnostic criteria whether we have meningeal hemorrhage or edema. I could supplement Dr. Prince's case with another one in which I advised Dr. Munro to trephine. He did so and found nothing, and the autopsy the next day revealed a large hemorrhage on the wrong side. In that case we secured the medulla and Dr. Thomas found a complete decussation, and since that time I have been very strongly in favor of the double trephining in doubtful cases. The last case operated on, where there was fracture at the base and convulsions beginning now on one side and now on the other, although we found a hemorrhage on the side where we went in I advised opening on the other side and that was done although there was no

hemorrhage of any amount there. The man made a perfectly good recovery.

DR. BROOKS: Dr. Bullard's criticism, that the dura was not left open is well made; but as a matter of fact, there was plenty of room between the sutures to allow of the escape of serum.

I cannot see the advantage of using a large trephine when, as in this case, you do not know whether you must explore in the region of the anterior, or posterior, branch of the middle meningeal. It would seem to me that by using a large trephine you would remove bone which might just as well be allowed to remain.

DR. WALTON: I judge from certain of the remarks that we were understood to deem convulsions essential to meningeal hemorrhage. This is by no means the case. The sentence which possibly gave rise to this misapprehension was as follows: "It must be remembered that meningeal hemorrhage is sometimes followed by paralysis without convulsions."

DR. ROBERT W. LOVETT read a paper entitled

THE PREVENTION OF FLAT-FOOT AND OTHER SIMILAR AFFECTIONS OF THE FOOT,

with the demonstration of a method of examining the feet.²

DR. E. H. BRADFORD: This method of mirror inspection of the sole of the foot is not only original on the part of Dr. Lovett, but it is of much value, opening a way to further investigations. The examination which Dr. Lovett has made has been chiefly on the foot in a standing position, but it is also of importance to know the shape of the foot in walking as well, for it has been proved by clay impressions of the feet that the pressure alters as the weight is thrown forward or backward and that flexible feet are altered in shape accordingly. This is to be considered in selecting the proper lasts for shoes. By a large portion of the community the front of the foot is not used to any extent, individuals standing bearing their weight chiefly upon the heel; for this reason distorted shoes with pointed toes cause but little discomfort. If the individual walks actively, the shoe should be so designed that the toes are not crowded and free action be possible especially for the great toe.

DR. DEWEY: At the hospital we find that a large number of the nurses at first complain that their feet are tired, but at the end of the first fortnight, as a rule, they get the boot prescribed; and after that their troubles rapidly cease in the majority of cases. The nurses, as a rule, are satisfied with the regulation boots. I think perhaps that we have been a little hypercritical watching for bad results and trying to get some for Dr. Lovett. In this we have almost entirely failed. The results to us at the hospital have been wonderful. Not a day has been lost by the nurses on account of their feet, whereas formerly a good many days were lost and some of the nurses had to leave the school. We are very grateful to Dr. Lovett for what he has done.

DR. LOVETT: In closing, I want to say that the child's foot shown is open to exactly the criticism that has been made. It is a very imperfect affair. The gentlemen who have not been in the business have no idea how difficult it is to get a boot carried through on any new lines. It has to be fought all the way, but I hope ultimately to be able to get boots of the sort Dr. Bradford speaks of.

MEDICAL TERMINOLOGY.

THE terminology of a rapidly progressing science must of necessity be in a continual state of instability. New terms are constantly being substituted for old ones, and the old ones are as persistently used as if no new ones had been called into existence. The result is an unfortunate state of affairs which seems as yet to be quite without a remedy. This is particularly true of medicine. Probably no other science contains such an array of words which inadequately or incorrectly represent the facts they were designed to describe. The respect engendered of age has apparently rendered many of them unassailable, and we find our recent text-books, the work of the most enlightened minds of our time, still burdened with terms, which have absolutely no claim to further respect.

The reason for the existence of these unfortunate terms is not far to seek. It must lie primarily in the fact that medicine has from the first been an inexact science, a reproach from which it has by no means yet freed itself, though at present making vigorous and praiseworthy efforts to atone for its former shortcomings. For two thousand years of its life medicine was largely speculative, and its devotees gave to the manifestations of disease and even to anatomical facts, names in accord with the vagueness of their methods of thought. A striking example of the speculative spirit in anatomical research is given by the curiously far-fetched and inappropriate names applied to many structures in the brain, for example, optic thalamus, gyrus fornicatus, nates and testes. Such terms are, however, harmless and do not stand in the way of progress. A much greater danger arose when observation came to be cultivated and the signs and symptoms of disease began to demand an attention often disproportionate to their worth. Then what we speak of as distinct diseases rapidly came into existence and fixed themselves deeply in the popular medical consciousness. The true nature of a disease process was

rarely understood, but for the purposes of practical medicine it was found convenient to group symptoms which were observed often to occur together, and usually with undue haste to dub such a collection with some name vaguely indicative of its character. In this way diseases have been born: many of them are destined to live, and some to die under the more exact criticism which we are now able to bring to bear upon them.

It was inevitable that names, given from clinical observation merely, should fail to express the essential feature of the underlying morbid process, and that an absolutely undue weight should frequently be attached to insignificant or unessential symptoms. The tendency has been to exalt symptoms and obscure processes, which must constitute the real disease. This clinical spirit has undoubtedly led to very great advances in our knowledge by directing attention to underlying causes, but it has also burdened medical literature with a vast number of so-called diseases, which it has been the laborious work of the laboratory to classify or else to discard. It is, however, a curiously difficult matter to rearrange or reclassify on a scientific basis the clinical observations which have extended over a long period of years. Locomotor ataxia and paralysis agitans will, no doubt, long be known under these inadequate names, even though we recognize that neither the ataxia nor the tremor are essentially important symptoms of the respective diseases. It is a matter for congratulation that many morbid conditions are known by the names of their discoverers rather than by a more or less unimportant symptom. As a preliminary step in the investigation of a disease it is a relief not to be prejudiced by an obtrusive symptom or sign. Bright's disease was better than albuminuria until we knew what the disease really was, and Landry's paralysis is infinitely more satisfactory than acute ascending spinal paralysis, and much less prejudicial to our future investigations, inasmuch as it does not always ascend, and certainly is not always spinal and probably does not exist at all as a distinct disease. Had Landry never lived it is doubtful whether his paralysis would ever have been described. However this may be, it is much more satisfactory in a case of such extreme vagueness to avoid a term which attempts to dogmatize upon what it is our professed object to investigate. We want to know what this peculiar paralysis is, and why it exists, and whether it has in its manifestations any thing which should dignify it as a distinct disease entity. Its inaccurate designation as acute and ascending and spinal, begs the entire question. Addison's disease is certainly a sufficient designation until we learn, as we seem about to do, what the essential cause of the symptoms is. The advent of pathological research has done much toward modifying clinical zeal and establishing on a more accurate foundation the boundaries and particularly the causes of disease.

With the growth of scientific investigation, however,

an array of new terms has come into use, and associated itself not always happily with the prevailing clinical nomenclature, usually to the advantage of neither. The result has been a curious and unsatisfactory mixture of words, partly pathological and partly clinical and popular, so that we are further than ever from a uniform terminology. Our knowledge has progressed to such a degree that a classification of certainly a large number of diseases either from a pathological or etiological point of view is possible, and yet we seem further than ever from such a consummation. Attempts at mutual agreement prove futile; conservatives continue to use the hopelessly bad terms that their fathers used before them, and radicals are coining new words of exact meaning in such abundance that it is quite impossible to follow them. Unless something be done and that quickly, it appears inevitable that the common ground upon which we now stand, will grow more and more uncertain under our feet, and that we shall have no firm place upon which to step. It is altogether to be hoped that the conservative element in the profession will renounce the use of obsolete terms, and still more to be hoped that enthusiasts for reform will moderate their zeal for a new terminology to those terms which are needed and essential. With the clearer conception which we are each day getting, of diseases as processes, manifested clinically by certain symptoms, it would seem not without the bounds of possibility that a nomenclature might ultimately be adopted which would hurt no one's prejudices and be decidedly beneficial to the cause of true progress. We regret to note that that time is not yet here.

TOO MUCH MAJOR OPERATING IN GYNECOLOGY.

IN these days when the medical profession is devoting so much attention to the major operations on the female pelvic organs, operations looking to the removal of the uterus, ovaries or tubes, or to their fixation in more or less abnormal positions in the body, it is not amiss, in the interests of conservatism at least, that we should pause a little and emphasize certain fundamental principles of gynecology: such as making a careful investigation in every case of the particular points in which the pelvic structures differ from the normal, and then endeavoring to restore them as far as possible to that normal condition.

The medical journals are full of the descriptions of new operations, a vast majority of which have for their object either the removal of organs or an improvement on Nature's handiwork. Operators wish to "build up a perineum," or to stitch the uterus to the abdominal wall or to the bladder. It does not seem to occur to the ingenious originators of these procedures that they are undertaking a large contract in trying to improve on Nature. Instead of taking a receptive and scientific attitude and trying to search out Nature's methods, they assume knowledge and declare that they can do better.

When a prominent operator advocates "slipping out" a uterus because it is subinvolved and the seat of endometritis, and another operator is in favor of amputating the cervix as a routine procedure instead of performing trachelorrhaphy, it may be that these practitioners are doing the best that can be done for their patients under the circumstances; at all events it is fair to assume that they think they are doing so. But a large body of the profession will always query, "Why should a woman lose her uterus or have her cervix cut off, with all that these mutilations imply, because the operator finds it easier to remove structures than he does to take the time and trouble necessary for the proper understanding of the more tedious and less brilliant methods of repair?"

When tyros in the art of diagnosis, emboldened by the lessened mortality of the present aseptic technique, rush into major operating the interests of the patient suffer. Many of the hospital operators and teachers help these tyros to a knowledge of the steps of certain operative procedures only to find these same men coming back to them after a longer or shorter period and saying, "Doctor, I know how to do such and such an operation, but I can't tell in what cases it is indicated and my results have been bad." How much more rational to begin at the beginning!

We believe that the diagnostic skill of the average practitioner in this department of medicine is constantly improving; but to be convinced that there is room for still further improvement the doubter has only to follow for a short time one of the out-patient clinics of a metropolitan hospital and hear there from the patients some of the diagnoses made and treatment advised by a large number of practitioners, all of whom probably are not always incorrectly reported. We are credibly informed that, even now in this enlightened age, a considerable number of patients presenting themselves at our hospital clinics for treatment for injuries of the pelvic organs due to child-bearing tell the old story that their doctors did not examine them after the puerperium. In other words, their medical attendants are pursuing the old policy of trusting to luck, perhaps fearing censure for injuries discovered, but more likely too busy to do their work thoroughly.

Early recognition of bad tears of the cervix and of the pelvic floor, inflammatory affections of the endometrium and tubes and ovaries, dislocations of the uterus and ovaries that do not right themselves in a reasonable time, if discovered and treated promptly, not only do away with the need of many operations but will prevent a large number of patients from becoming debilitated and neurasthenic — conditions of body and mind from which operations alone, be they ever so successful, will not lift them.

We should welcome a return of gynecology to its older and more natural channels. The profession at large, dazzled for the time by the brilliant feats of abdominal surgery, should not forget that gynecology is something besides abdominal surgery; and the general practitioner should be ready to follow the special-

ist, prepared to investigate and treat the diseases of the female pelvic organs according to well-founded principles of the art.

DR. DOTY'S REPORT ON PLAGUE ANTITOXIN.

ON March 26th, Dr. A. H. Doty, Health Officer of the Port of New York, made a report to President Wilson of the Board of Health, in which he states that early in February a temporary laboratory was established on Swinburne Island, under the direction of Dr. T. D. Fitzpatrick, for studying plague bacilli and, if possible, producing an antitoxin similar to that of Dr. Yersin, of the Paris Pasteur Institute, in his researches at Hong Kong.

The experiments were inaugurated February 17th, when animals were procured for the purpose. A horse was inoculated with a culture of the bacillus on February 26th, and the inoculations were repeated on March 4th and 9th. For the purposes of determining how early the serum of the animals might have acquired antitoxic properties, about one pint of blood was drawn from the horse on March 15th, and from this half a pint of serum was obtained. One cubic centimetre of this was injected into each of a number of white mice, and after thirteen hours the mice were inoculated with a culture of the plague bacillus. All of the animals lived; but several of the mice which had been inoculated with the plague bacillus at the same time died from the effects of the disease thus induced.

Tests were also made to ascertain the curative efficacy of the serum, but these did not prove as satisfactory as the prophylactic experiments. As a rule, however, the antitoxin had the effect of prolonging life to some extent, and in one instance the animal recovered. These tests were made by inoculating mice with the plague bacillus (which, if uninterfered with, destroyed life in about twenty-four hours), and afterwards at intervals of from three to twelve hours from the time of the injection, treating them with one cubic centimetre of the antitoxic serum.

Dr. Doty concludes that these experiments indicate that the serum of the horse treated in the manner described is surely both preventive and curative, and states that further investigations will be made in the same direction. The *Boston Herald* suggests that this particular serum should be regarded as an antidote, rather than an antitoxin.

MEDICAL NOTES.

A SECOND CONGRESS OF RAILWAY AND MARINE HYGIENE. — A Second International Congress of Sanitation and Hygiene of Railways and Navigation will be held at Brussels during September, 1897. The preceding Congress at Amsterdam was of scientific interest, and the next Congress has the support of the Belgium government. Those wishing to attend the Congress or obtain information regarding it should apply to Dr. J. de Lantsheere, rue de l'Association 56, Brussels.

PROFESSOR LIEBREICH HONORED BY THE FRENCH.—Prof. Oscar Liebreich, director of the pharmacological laboratory of Berlin University, has received the officer's cross of the French Legion of Honor.

FINED FOR EXPECTORATION.—In Philadelphia a passenger has been arrested and fined five dollars for persistently spitting on the floor of a street-car, though requested by the conductor several times not to do so.

A BRAVE "NON-COMBATANT."—Charles James Fyfe, M.D., an English naval surgeon, was killed during the Benin expedition, being shot on the field while caring for a wounded officer of marines. Singular bravery and devotion is sometimes displayed by "non-combatants," and that in cold blood.

UNVEILING OF THE GROSS STATUE.—The American Surgical Association and the Alumni Association of the Jefferson Medical College of Philadelphia have issued invitations to the unveiling of the statue of the late Prof. Samuel D. Gross, M.D., near the Army Medical Museum, Washington, D. C., on Wednesday, May 5th, at five p. m.

PLAGUE IN INDIA.—Plague is reported spreading rapidly in Gujarat, an Indian province north of Bombay, and causing many deaths and there has been a considerable increase in the districts of Surat, Sukkur, Thana and Hyderabad. The death-rate in Bombay is decreasing slightly. The total number of cases up to March 11th was 9,032 and 7,546 deaths had resulted. In the whole presidency, to this date, there had been 14,856 cases of the plague reported, and 12,204 deaths.

LADY DOCTORS IN GREECE.—Two young Greek ladies, the sisters Angelica and Alexandra Panagiotatos, recently took their degrees as doctors of medicine in the University of Athens. The elder is aged twenty-two and the younger twenty. They are natives of Corfu, where they began their studies, continuing them later in the French School at Athens, and afterwards in the university of that classic city.

HAFFKINE'S PROPHYLACTIC PLAGUE SERUM.—Dr. Haffkine has recovered from his recent illness; and it is reported that up to March 17th he had inoculated 2,790 persons with his prophylactic serum against plague. It is said that none of those inoculated while free of plague have died of the disease and but few have been attacked, and that all attacked subsequent to inoculation except three have recovered. Dr. Yersin is reported in the daily papers to be very successful with his curative serum, failure occurring only in those who were moribund when inoculated.

SCURVY ON A NEW YORK SHIP.—The ship *T. F. Oakes* recently arrived at New York from Hong Kong, several weeks overdue, twelve of her crew very sick with scurvy, and five having died on the voyage. Only three or four men were fit for duty; and the captain's wife, who beside her husband was the only well person on board, had been taking her turn at the wheel. A supply of lime-juice or vinegar would probably have saved a great deal of suffering. The

shipping commissioner has begun an inquiry into the causes of a state of affairs which, though common enough fifty years ago, is without excuse to-day.

A PHYSICAL EXAMINATION REQUIRED BEFORE MARRIAGE.—A member of the Texas Legislature has prepared a bill, according to the *Journal of the American Medical Association*, that he thinks will greatly benefit his fellow-citizens. The bill, if passed, will revolutionize the marriage license system of the State. The intending groom must previously undergo a thorough physical examination at the hands of a competent medical practitioner in good standing, and be possessed of said physician's sworn certificate of physical soundness. The prospective bride must also have undergone a similar ordeal and a like certificate in her behalf must be submitted. Not only this, but both parties "to the contract" must file sworn statements attesting the fact that neither of them are subject in a hereditary way to any disease that might in like manner transmit tendencies thereto in their probable offspring. The county clerk must then satisfy himself that these "credentials" are perfect before granting the license to marry. Should he give it without having these evidences of "fitness" presented to him, he would be held criminally liable.

THE MECCAN PILGRIMAGE.—The Indian Government has ordered that no residents of Bombay Presidency or Sindh, and no person who has entered Bombay Presidency or Sindh, with the object of proceeding on a pilgrimage to the Hedjaz, shall be allowed to embark from any port in British India for the purpose of making a pilgrimage to Mecca. All pilgrims who have entered these presidencies are to be placed in a camp of observation until the medical officer in charge has decided that there is no further risk of plague breaking out among them, and then sent to their homes. Local governments are directed to segregate, for at least seven days, all persons who intend making the pilgrimage; and when the Commissioner of Police at Calcutta signifies that a ship is ready to sail, each batch of pilgrims is to be sent in a special train direct to Diamond Harbor, there to embark at once. Thus, although the pilgrimage is forbidden from the plague-stricken districts, it is not peremptorily prohibited from all parts of India, although the Government is doing all in its power to induce the Mussulman community to forego the pilgrimage altogether. The French Government has forbidden the pilgrimage from Algeria and Tunis, and the Sultan of Morocco has forbidden pilgrims to leave that country for Mecca.

NEW YORK.

THE BOARD OF HEALTH OF GREATER NEW YORK.—The charter of the Greater New York, as finally adopted by the Legislature on March 24th and 25th, provides that the Board of Health of the city shall consist of five members, namely, the Health Officer of the Port, the President of the Board of Police, and three Commissioners (one more than in the present

arrangement), to be appointed by the Mayor. Two of these three commissioners are to be medical men and the third a layman, and the last-named shall be the President of the Board. The term of office of the appointed commissioners is six years. The President is to receive an annual salary of \$7,500, and the other two, salaries of \$6,000. The Board of Health is to have the same general powers as the old Board, and officers will be established in all the five burroughs into which the consolidated city is divided. The Sanitary Superintendent is to be the executive officer of the Board, and will receive a salary of \$6,000. The salary of the Registrar of Records is fixed at \$4,000. There will be three Commissioners of Charities (who will direct the management of all the public hospitals): — one for the burroughs of Manhattan and the Bronx (Manhattan Island and the present district annexed from Westchester County on the north), at a salary of \$7,500; one for the burroughs of Brooklyn and Queens (embracing Brooklyn and all the territory on Long Island included in the limits of the consolidated city), and at a salary of \$7,500; and one for the burrough of Richmond (Staten Island), at a salary of \$2,500. The Commissioner for the burroughs of Manhattan and the Bronx is to be President of the Board of Public Charities.

A LARGE CLASS GRADUATED FROM BELLEVUE.— On March 22d a class of 133, the largest for some time past, was graduated from Bellevue Hospital Medical College, which several years ago gave up the practice of holding public commencement exercises. Twenty-five States were represented by the graduates, and twelve of the class were foreigners. The examinations of Henry Ritter, of Massachusetts, and C. E. Pierce, of New York, entitled them to positions on the house-staff of Bellevue Hospital. The veteran of the class was Dr. W. E. Moore, of South Dakota, who is said to be approaching sixty years of age.

DEATH OF DR. CLARK WRIGHT.— Dr. Clark Wright, a son of the late Dr. Clark Wright, and a member of the Surgical Staff of Roosevelt Hospital, died on March 17th. He was born in 1859 and was a graduate of Yale University and of the College of Physicians and Surgeons, New York.

COMMENCEMENT OF THE AMERICAN VETERINARY COLLEGE.— The twenty-second annual commencement of the American Veterinary College was held at Chickering Hall, on March 26th, when degrees were conferred by Dr. Fauvel D. Weiss, President of the Board of Trustees, upon a graduating class of twenty-three.

A HANDSOME CONTRIBUTION TO HOSPITALS.— The Committee of the Hospital Saturday and Sunday Association appointed for the purpose met at the Mayor's office on March 26th and distributed the handsome sum of \$50,000, the proceeds of the recent annual collection for hospitals. Among the institutions allotted more than one thousand dollars were the following: The Montefiore Home for Chronic In-

valids, which received \$5,000; Mount Sinai Hospital, \$5,000; German Hospital, \$3,125; St. Luke's Hospital, \$3,015; Hospital for Ruptured and Crippled, \$3,018; Roosevelt Hospital, \$2,948; St. Mary's Hospital for Children, \$2,368; Post-Graduate Hospital, \$1,842; Home for Incurables, \$1,417; Orthopedic Hospital, \$1,217; St. Mark's Hospital, \$1,163; Woman's Hospital, \$1,038.

PROPOSED LEGISLATION AGAINST THE ABUSE OF MEDICAL CHARITY.— An organization known as the New York Medical Society for Advancing the Practice of Medicine, composed of physicians residing in the southeastern district of the city has had introduced in the Legislature a bill designed for the suppression of the abuse of medical charity in dispensaries, which has met with the approval of a number of prominent members of the profession, and which contemplates the adoption of more sweeping measures than have ever before been attempted. Among its more prominent provisions are the following:

That no person who is not a poor person shall be treated in a dispensary, except in cases of emergency, and that no compensation whatever shall be received for treatment or medicine furnished by a dispensary. That all persons applying for treatment at a dispensary must produce a signed certificate from the owners of the premises where they reside, from the captain or other official in charge of the police precincts in which they reside, from the aldermen of the district, or from some charity organization, to the effect that they are unable to pay for treatment or medicines; such certificate to be of no effect after thirty days from the date of its issue. The signing of such a certificate by any one knowing that the applicant for free treatment is not a poor person renders the signer punishable for misdemeanor.

That a commission to be known as the Medical Board for the Supervision of Dispensaries within the City of New York, composed of representatives of a number of prominent medical societies and of the united charities of the city, shall have power to make and enforce such rules and regulations as may be necessary for carrying out the provisions of the act.

That the authorities of any dispensary violating any such rules or regulations may be prosecuted by the Board, or any officer thereof, and, upon conviction, be deemed guilty of a misdemeanor and punished by a fine of not less than \$50 or more than \$250, or by imprisonment for not less than one month or more than six months, or both such fine and imprisonment for the first offence and six months' imprisonment for each subsequent offence.

That the husband and wife shall be jointly and severally liable to pay for professional services of a physician rendered to them, or either of them, or any member of their family, and the joint or several property of the husband and wife shall be liable to levy and sale under an execution upon such judgment, except such property as may by law be exempt from levy and sale under an execution.

Miscellany.

THE COMPULSORY REPORTING OF TUBERCULOSIS.

THE committee of the New York Academy of Medicine appointed at the January meeting for the consideration of tuberculosis, of which Dr. E. G. Janeway was Chairman and Dr. T. Mitchell Prudden Secretary, presented to the Academy on March 18th the following statements, which were accepted and adopted:

(1) In the opinion of this committee the board of health might wisely delay the enforcement of compulsory notification, but should adopt more stringent measures for the care of sputum in factories, workshops, tenement-houses, ferryboats, places of public assemblage and public conveyances.

(2) In the opinion of this committee the establishment and maintenance by the city of a hospital or hospitals, to which indigent tuberculous patients may be admitted, is advisable.

(3) This committee recommends the appointment by the legislature of a commission for the establishment and management of sanatoria in healthy country districts in this State, for the care of the indigent tuberculous patients in the early stages of the disease.

(4) This committee would commend to the State board of health the importance of the careful regulation of the sanitary condition of hotels and sleeping-cars throughout the State.

At the Medical Society of the County of New York on March 22d, the following resolution was adopted:

Resolved, That in the judgment of this Society the recent edict of the health department in relation to the compulsory reporting of cases of tuberculosis is unnecessary, inexpedient and unwise.

SELF-PROTECTION BY THE MEDICAL PROFESSION IN THE DISTRICT OF COLUMBIA.

THE following recommendations were adopted by the Medical Association of the District of Columbia, on February 16, 1897:

(1) That every institution for medical charity shall require from every applicant for relief in a hospital or dispensary a written certificate to be obtained as hereinafter provided. Emergency cases are to be excepted from the operation of this rule.

(2) That such certificate be obtained from physicians to the poor, the Board of Associated Charities, and any registered physician.

(3) That sick and injured persons found upon the streets, in the stations, or elsewhere, who require immediate treatment shall be carried to the Emergency Hospital, or the nearest hospital having an emergency service, or to their homes, if so directed by the patient or his friends.

(4) That emergency patients shall not be detained longer in such institutions than the necessity of the case imperatively demands, but shall be discharged from the service and sent to their homes or to some public hospital, as the patient may elect.

(5) That members of this Association shall be entitled to the privilege of attending private patients occupying private rooms in any of the public hospitals of this city.

(6) That in future the members of the medical staff of hospitals, when attending medical or surgical cases in private pay-rooms, shall insist upon proper payment for their services except in the case of patients who are clearly unable to pay for the same.

(7) That whenever the medical staff or a majority thereof of a hospital or dispensary resigns, and when, after due hearing, this Association finds that the resignations were for just and sufficient cause, it shall be forbidden for any member of this Association to accept a position on the staff of said hospital or dispensary.

(8) That whenever one or more members of the medical

staff of a hospital or dispensary are dismissed, and when, after due investigation, this Association finds that such dismissal was without just and sufficient cause, it shall be forbidden for any member of this Association to fill the vacancy created thereby.

(9) That complaints made under Rules 7 and 8 shall be made in writing to the Standing Committee, which after due consideration shall report its findings to the Association.

CONGENITAL PROLAPUS UTERI.

CASES of congenital prolapse of the uterus are so rare that the report of two cases by Ballantyne and Thompson,¹ is of marked interest. Illustrations from frozen sections of the pelvis in one case add considerably to the interest of the paper. The condition is always found to be associated with lumbo-sacral spina bifida, and frequently with other anomalies. The chief points of interest in connection with the cases are given in the following summary which is appended to the article:

(1) A real downward displacement of the uterus present at birth or appearing during the first week of life is a well-established anomaly, but one of the greatest rarity, only eight instances having been recorded.

(2) It is to be distinguished from the so called congenital hypertrophic elongation of the cervix, but may be accompanied by a certain degree of cervical hypertrophy.

(3) It is practically constantly associated with lumbo-sacral spina bifida and rectal ectropion, and very often with clubbing of the feet; less common complications are hydrocephalus and hypertrichosis.

(4) All the patients thus affected died soon after birth; but it is reasonable to attribute the fatal issue to changes in the spina bifida rather than to the uterine prolapse.

(5) The prolapse may be complete or incomplete, and an edematous swelling of the prolapsed part commonly exists; but the anomaly does not give rise to a well-marked train of symptoms, for in some instances even the bladder and rectal functions have been normally performed.

(6) Probably the chief causal factors are the results of disturbance of the innervation of the parts in consequence of the spina bifida, which seems generally to have been a myelomeningocele; but other etiological circumstances doubtless exist, such as increased abdominal pressure, the abnormally large size of the pelvic canal, and enlargement of the uterine cervix or body, or both.

Correspondence.

THE SEMI-CENTENNIAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

PHILADELPHIA, March 24, 1897.

MR. EDITOR:—May I call the attention of those of your readers who are thinking of coming to Philadelphia to attend the semi-centennial meeting of the American Medical Association to be held June 1, 2, 3 and 4, 1897, that there will be in addition to the American Medical Association at the same time a large mercantile convention which will to a certain extent utilize a considerable number of the rooms in the various hotels.

For this reason it is advisable that physicians who intend to be present at the meeting should write at once to one of the following hotels, engaging such rooms as they desire at the rates named:

Hotel Walton, Broad and Locust Streets: \$1.50 and upwards per day, European plan; \$1 and upwards per day, American plan.

¹ American Journal of Obstetrics, February, 1897.

The Colonnade, 15th and Chestnut Streets: \$1 and upwards per day, European plan; \$3 and upwards per day, American plan. The Lafayette, Broad and Chestnut Streets: \$1 and upwards per day, European plan. Table d'Hôte: breakfast 25c. to \$1; luncheon 75c.; dinner \$1.25.

The Bingham House, 11th and Market Streets: \$2.50 and upwards per day, strictly on the American plan.

Hotel Tenton, Broad and Spruce Streets: \$2 and upwards per day, European plan; \$4 and upwards per day, American plan.

The Continental, 9th and Chestnut Streets: \$3 and upwards per day, strictly on the American plan.

The Windsor, 11th and Filbert Streets: \$1 and upwards per day, European plan; \$2 per day, American plan.

The Stratford, Broad and Walnut Streets: \$1 and upwards per day, European plan only.

Girard House, 9th and Chestnut Streets: \$2.25 to \$3 per day, strictly on the American plan.

Hotel Hanover, 12th and Arch Streets: \$2.50 per day, strictly on the American plan.

Aldine Hotel, Chestnut Street above 19th: special rates to members of the American Medical Association, \$2.50 per day on American plan; \$1 to \$3 on the European plan.

The price quoted in each instance is for one person only. Rooms commanding only the lowest price are naturally limited in number. It is especially desirable that each member intending to be present at the meeting shall personally, or by letter, make his arrangement with the hotel at which he desires to stop.

It is worthy of note that the rate of \$1.50 per day at the Hotel Headquarters, the "Hotel Walton," is the rate for two people in one room.

All these hotels are within a few blocks of the meeting places and most of them are within two blocks.

As a sub-committee of the general Committee of Arrangements has arranged clinical courses in all branches of medicine at the various teaching institutions and large hospitals during the week prior and following the week of the Association meeting, it has been thought a considerable number of physicians would be glad to embrace the opportunity of "brushing up" upon the various branches by attendance on these courses, for which no charge will be made by the gentlemen giving them; and as their stay in this city will therefore be more than a few days, it has occurred to the Committee that some of the visiting physicians may wish to take rooms at some good boarding-house. The Chairman of the Committee on Reception and Accommodation, Dr. G. E. de Schweinitz, 1401 Locust Street, will be glad to send the addresses of such boarding-houses to gentlemen desiring to stay here for a week or more.

The large number of gentlemen who have already signified their intention of attending the meeting, the very large number of able and interesting papers already placed upon the programme, indicate that this will be the most important meeting which the Association has ever had, and it is hoped that every physician who is a member of a regularly organized County Medical Society will make an effort to attend.

The meeting halls for the various Sections are situated so close to one another that different papers in different sections can be readily listened to during a single morning's session by those who do not wish to devote their time to one particular specialty.

Very truly yours,

H. A. HARE,

Chairman of the Committee of Arrangements.

METEOROLOGICAL RECORD

For the week ending March 20th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

BROUGHT OUT BY A LEADING QUESTION. — The Vienna correspondent of the *Lancet* is authority for the following story: "Medical circles in Vienna have been much amused at an answer given by a student who was being examined in pathological anatomy and was asked to name the organs of the body in which cysts most commonly occur. He enumerated several, but omitted to mention the ovary, whereupon the examiner good-naturedly said: 'Try to think of an organ which you do not possess,' and the candidate who was of Jewish extraction, immediately replied, 'Oh, the prepuce!'"

an estimated population of 10,992,524, for the week ending March 13th, the death-rate was 18.6. Deaths reported 3,949; acute diseases of the respiratory organs (London) 344, whooping-cough 83, measles 79, diphtheria 72, diarrhea 39, scarlet fever 38, fever 22.

The death-rates ranged from 12.2 in Newcastle-on-Tyne to 25.3 in Bolton; Birmingham 18.5, Bradford 19.2, Bristol 24.5, Croydon 15.9, Halifax 18.0, Leeds 19.6, Leicester 18.2, Liverpool 23.3, London 18.4, Manchester 23.0, Nottingham 17.5, Portsmouth 16.6, Sheffield 16.9, Sunderland 15.0, West Ham 15.1.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 20, 1897, TO MARCH 25, 1897.

CAPTAIN CHARLES WILLCOX, assistant surgeon, is relieved from duty at West Point, N. Y., to take effect upon the expiration of his present leave of absence, and ordered to Fort Bliss, Texas, for duty at that post, relieving CAPTAIN OGDEN RAFFERTY, assistant surgeon.

CAPTAIN RAFFERTY, on being thus relieved, is ordered to Willets Point, N. Y., for duty at that post.

The extension of leave of absence on surgeon's certificate of disability granted CAPTAIN EUGENE L. SWIFT, assistant surgeon, is still further extended one month on surgeon's certificate of disability.

FIRST LIEUT. FRANCIS A. WINTER, assistant surgeon, upon completion of his examination for promotion, ordered to West Point, N. Y., to report to the superintendent U. S. Military Academy, for duty at that post.

CAPTAIN NATHAN S. JARVIS, assistant surgeon, is relieved from duty at Willets Point, N. Y., to take effect upon the expiration of his present leave of absence and ordered to Fort Clark, Tex., for duty.

MAJOR HENRY S. KILBOURNE, surgeon, will be relieved from duty at Fort Clark, Tex., upon the arrival at that post of CAPTAIN JARVIS, and ordered to Madison Barracks, N. Y., for duty.

FIRST-LIEUTS. ISAAC P. WARE, ROBERT S. WOODSON and GEORGE D. DETHON, assistant surgeons, are ordered to report in person to LIEUT.-COL. DAVID L. HUNTINGTON, deputy surgeon-general, president of examining board, at such time as they may be required for examination for promotion.

A board of officers to consist of LIEUT.-COL. DAVID L. HUNTINGTON, deputy surgeon-general; MAJOR WALTER REED, surgeon; CAPTAIN CHARLES M. GANDY, assistant surgeon, is appointed to meet at the Army Medical Museum Building, Washington, D. C., on Tuesday, May 4, 1897, at 10 o'clock A. M., for the examination of such officers of the Medical Department as may be ordered before it to determine their fitness for promotion.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE TWO WEEKS ENDING MARCH 27, 1897.

D. N. CARPENTER, assistant surgeon, detached from U. S. Naval Laboratory and Department of Instruction, Brooklyn, N. Y., and ordered to the "Brooklyn," March 15th.

F. L. PLEADWELL, assistant surgeon, detached from U. S. Naval Laboratory and Department of Instruction, Brooklyn, N. Y., and ordered to temporary duty on the "Constellation," March 15th.

H. G. BEYER, surgeon, detached from the "Newark," March 17th, and ordered home to await orders.

A. W. DUNBAR, assistant surgeon, detached from the "Newark," March 17th, and ordered to the "Vermont."

M. H. SIMONS, surgeon, detached from Torpedo Station, Newport, R. I., April 15th, and ordered to the "Columbia."

E. Z. DEER, surgeon, detached from the "Columbia," on being relieved, ordered home and granted three months' leave.

J. M. MOORE, passed assistant surgeon, ordered to the "Alert," upon the arrival of that vessel at Mare Island, Cal.

L. W. SPRATLING, passed assistant surgeon, detached from the "Alert," upon being relieved, ordered home and granted three months' leave.

G. D. COSTIGAN, assistant surgeon, detached from Naval Laboratory and Department of Instruction, and ordered to the "Vermont."

C. A. SIEGFRIED, surgeon, detached from the "Massachusetts" and ordered to the Torpedo Station.

S. H. DICKSON, surgeon, detached from the "Texas," and ordered to the "Massachusetts."

W. R. DU BOSE, surgeon, detached from the "Terror," April 6th, and ordered to the "Texas."

OLIVER DIEHL, surgeon, detached from the Philadelphia Naval Hospital, April 5th, and ordered to the "Terror," April 6th.

T. C. CRAIG, surgeon, placed on the retired list from March 12th.

R. M. KENNEDY, passed assistant surgeon, detached from Norfolk Naval Hospital, April 3d, and ordered to the Philadelphia Naval Hospital.

D. N. CARPENTER, assistant surgeon, detached from the "Franklin," and ordered to the "Raleigh."

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday evening, April 5th, at 8 o'clock.

The subject of the evening will be: "The Significance of the Results of Radiographs in Bone Surgery." The leading paper will be presented by Dr. Wm. M. Conant, who will be followed by Drs. H. H. A. Beach, F. H. Williams, M. H. Richardson, E. A. Codman and J. E. Goldthwait.

Dr. M. H. Richardson will read a paper entitled, "A Case of Congenital Stricture of the Pylorus in a Boy of Seven; Pyloroplasty; Recovery and Restoration of Health."

JAMES G. MUMFORD, M.D., Secretary, 197 Beacon St.

THE SUFFOLK DISTRICT MEDICAL SOCIETY, SURGICAL SECTION.—The Section will meet at the Medical Library, 19 Boylston Place, on Wednesday evening, April 7, 1897, at 8 o'clock.

At 8 P. M. "Observations upon Recurrence of Stone in the Bladder," by Dr. A. T. Cabot. Synopsis of paper: The effect of ulcerated spots in the bladder in producing recurrence of stone. Conclusions as to appropriate treatment, based on some cases.

At 8.45 P. M. The presentation of pathological specimens by Dr. W. T. Councilman.

At 9.05 P. M. "The Prevention of Pneumonia after Anesthesia," by Dr. W. F. Whitney. Synopsis of paper: Pneumonia after ether is of the ordinary form and is due to the pneumococcus. This has been shown to be present in the months of many persons in health. Thorough disinfection of the month before anesthesia may destroy this source of infection. Dr. J. W. Elliot will open the discussion of this paper.

PAUL THORNDIKE, M.D., Secretary, 244 Marlborough St.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.—The Annual Conversational Meeting of the Society will be held in the Upper Hall of the College of Physicians, Northeast Corner Thirteenth and Locust Streets, on Thursday, April 22, 1897, at 8.15 P. M.

Dr. Ludvig Hektoen, Professor of Morbid Anatomy in Rush Medical College, will deliver an address, entitled "Segmentation and Fragmentation of the Myocardium."

After the meeting a reception will be tendered Dr. Hektoen at the University Club, 1316 Walnut Street.

A cordial invitation is extended to attend the meeting and the reception.

HARVARD MEDICAL ALUMNI ASSOCIATION LECTURES ON CLIMATOLOGY.

The third and fourth lectures on "Climatology and its Relations to Medicine," by Mr. Robert DeC. Ward, Instructor in Climatology in Harvard University, will be delivered at the Harvard Medical School on the successive Tuesdays, April 6th and April 13th, at 8.30 P. M.

Third Lecture, April 6th.—"The Distribution of Rainfall over the World; Its Relation to the General Wind Circulation, and the Resulting Climatic Conditions; the Controls of Climate; the Climatic Zones."

Fourth Lecture, April 13th.—"The Physiological Effects of Temperature, Pressure and Humidity; Acclimatization; A Sample of Climatic Description; The Climate of New England." Illustrated by colored charts.

DIPHTHERIA-ANTITOXIN.—AMERICAN PEDIATRIC SOCIETY.

The Collective Investigation (report) will be kept open until April 10th, in order to secure a return of all cases beginning before April 1st.

The Committee desires to express its appreciation of the trouble and pains the members of the profession have been willing to take in this matter. The return-blanks are more understandingly made out than in the first report.

RECENT DEATH.

GEO. B. TWITCHELL, M.D., of Keene, N. H., one of the leading practitioners of New Hampshire, died at Keene, March 30th, aged seventy-seven years. He served during the war as surgeon of the 13th New Hampshire Volunteers and was promoted surgeon-in-chief of the 17th corps, with the rank of major. He was for years president of the board of trustees of the New Hampshire Asylum for Insane, and was instrumental in the establishment of the Elliot Hospital in Keene. He was a Republican, and had held almost every office within the gift of citizens. He leaves two sons, Dr. George P. Twitchell, of Greenfield, and Dr. Edward T. Twitchell, of Ashmont, and two daughters.

Address.

ON THE DUTIES OF A MEDICAL EXAMINER.¹

BY HOSEA M. KNOWLTON,
Attorney-General of Massachusetts.

MR. PRESIDENT AND GENTLEMEN:—My experience is that success grows and results, much more from men than from machinery, in any department of human activity, whether in business or in the workings of laws. It is the men who are entrusted with the work, rather than the machinery that is devised, that make or mar results.

I am glad to say this, gentlemen; although I have been an associate member of your organization for many years, it is the first opportunity that I have had of putting in formal shape my testimony to the very commendable exertions of the members of this body, and of the medical examiners throughout the State, to enforce the provisions of this law in the interest of justice in the Commonwealth.

It may be that my experience has been larger than that of living men. I have had to do directly and indirectly with the trial of thirteen indictments for murder, and the investigations of many more cases, and I have uniformly found the medical examiners with whom I have been brought in contact, whether in my own section of the State or elsewhere, to have that understanding, that intelligent understanding, of the duties imposed upon them by the Medical Examiner Act, that was necessary for its success.

As you know, the medical examiner system succeeded a system which had fallen into disrepute, and which had become worse than obsolete. This act was an immense advance in the business of detecting and punishing crime; and yet this act would not have been a success had it not been for the character of the men who enforced it.

That leads me to observe, also, that I am addressing a body of men upon the duties of an office which, so far as I am able to understand by my experience, they already well know. I also observe that from time to time, beginning perhaps with Mr. Tyndale, the author of the act and its most earnest promoter, who addressed this body twenty years ago, and from time to time by other officers concerned in the prosecution of crime, the duties of medical examiners have been very fully gone into; and I hardly hope to add anything to the intelligent discussion already had. But I am told by your secretary, who is responsible I suppose partly for my being here, that from year to year new members are added to your body who very seldom read the musty records of the past, and that it may not be entirely useless to consider some of the difficult features of the law.

It has been said over and over again, and the remark has been put in capital letters in every case where your body has been addressed, that the main purpose of the law is the detection of crime. I assent to that statement, but conceive that the duties of the medical examiner are more accurately expressed if, instead of saying that "the purpose of the law is the detection of crime," we say that its real object is the ascertainment of the question of guilt or innocence. You can easily see the distinction, gentlemen. By far the greater number of deaths that occur, not from disease but from injury or even from violence, are not

tainted with crime. But it is more important, perhaps, it is at least as important, that the fact of innocence should be determined as the fact of crime. And if that is understood, some questions which I am told, Mr. President, are troubling this body, will thus be easily solved.

It is not a question, when a medical examiner is asked to have a view, whether it will probably result in finding crime. The question, the only question, should be, Is there any ground of suspicion of crime? And the medical examiner discharges his duty as effectually when he, by his investigations, dissipates that suspicion and establishes innocence.

A woman dies from some disease which leads the neighbors and friends of the family to suspect an abortion has been committed. The medical examiner makes his examination, his view, or even his autopsy, if necessary, and establishes that that suspicion is unfounded. That result is as important to the Commonwealth as it would have been had he found crime connected with it. I speak of this because it has been suggested to me by more than one member of this Association that the question of whether to take a view, or not, is sometimes considered with reference to its expense. I will speak of that a little more, later; but I now refer to that in connection with the proposition that I am endeavoring to make, that it is not a question probably of the detection of crime. It is as much the establishment of innocence where crime is suspected by anybody.

I judge from some things that have been said, and no less by some of the addresses that have been made to this body in years gone by, that the first stumbling-block in the way of the intelligent comprehension of the "Medical Examiner Law" is the expression, "death by violence." It is said that the term "violence" has been variously defined. And it may not be improper for me to try my hand at it. The word "violence" has a number of meanings, and perhaps in common conversation it may mean "force of any kind, innocent or guilty." But in the few moments that I was able to give to the preparation of this rather informal address (for I was told I could give that sort of address) I have examined the definitions of the word "violence," and find that in the "Century Dictionary" this definition, (in law that is, the definition that obtains in law), is "Any wrongful acts of one person whereby either he or his instrument of wrongdoing is brought in contact with the limbs or body of another person." Also "unlawful use of physical force." In the "Standard Dictionary" the same definition is given, "force unlawfully exercised." With that understanding, there is no difficulty in the jurisdiction, so to speak, the province of the medical examiner. He is to ascertain whether in any given instance death is the result of "force unlawfully exercised."

The analysis which I have attempted to make is probably not wholly logical or necessarily conclusive. It may not fulfil the etymological definitions of the terms used, but I divide them in this way: A death may be "natural" or "unnatural." As I say, that definition may be criticised according as you define the term "natural" or "unnatural." But those whom I am addressing have no difficulty in understanding what I mean. They are perhaps the most convenient words. If the death is "natural," there is no work for the medical examiner. He is only called upon to consider the "unnatural" death. "Unnatural" deaths may also

¹ An Address before the Massachusetts Medico-Legal Society, February 3, 1897.

be divided into two kinds: those which, for want of a better term, I have described as "accidental," and those which are the result of "violence." Here, again, part of the work or province of the medical examiner develops. In an "unnatural" death, if it results from accident, the medical examiner is relieved, if that is thought to be a fact. That leaves him only with deaths by "violence."

According to the definition now given, which may be divided into two classes, in our acceptance of the word, and as to which I am bound to say some confusion has arisen, even in the mind of the author of the act himself, "death by violence" may be when the "violence" is self-inflicted, or when it is inflicted by another. I do not understand that, if it is clearly established that the violence is self-inflicted, there is any occasion for the medical examiner to go further. Probably the confusion arises from the fact that, in practice, when it is once ascertained that the man contributed to the death, it is extremely difficult in most cases to determine in advance the evidence, beyond that of the medical examiner, whether the man or person who inflicted the violence was the victim of a homicide, or not.

But, in strict analysis, we reduce the duties of the medical examiner to "unnatural violent deaths," using the word "violence" as being usually limited to those in which the "wrongful acts of another, unlawful, forceful acts of another, contributed." Of course, that does not always mean murder, as I need scarcely say to you. It may mean manslaughter, as where, by reason of insufficient care exercised by one having the duty of caring for a person under his charge (as by a father to his child) or neglect or exposure, admitted or allowed or practised, death results. There is no blow struck, but the crime has been committed — the crime of manslaughter. Again, the supposed instance I cited a few moments ago (death resulting from abortion), which is not murder or manslaughter, but it is a crime which it is your business in ascertaining to detect and punish. The medical examiner, then, having jurisdiction, having in his province the investigation of all cases of death supposed to be by violence, is charged with the duty, with the responsible duty, of first establishing the fact either of innocence on the one hand or probable violence on the other hand, and the getting and preserving what is by far the most important evidence, that is, a death by violence.

You will observe that I, on the one hand, make your investigations final when the innocence is established, and on the other hand, only a probable conclusion when crime is ascertained. Of course, the machinery of the law steps in after your result, and determines the question of "guilt" or "innocence" in the usual channels. The medical examiner presents his investigations, what is before him, to the extent of reporting that in his opinion there has been crime, and then turns the matter over to another.

Now, what is the medical examiner's business? The law limits him by Section 10, of Chapter 26, of the Public Statutes: "He shall make examination upon the view only of such persons as are supposed to have come to their death by violence." That is to be considered in connection with the next section, which provides that "When he has notice that there has been found, or is lying, within his county, the dead body of a person who is supposed to have come to his death by violence."

Who is to make the supposition? I answer, anybody, anybody. It is not confined to an attending physician; it is not confined to the officers of the law. It is broad enough to include any good citizen who has knowledge enough under the circumstances to entertain a reasonable suspicion. Bear in mind that the object of the whole proceeding which is initiated by you is, if your results are clear as to innocence or guilt — the whole object is ascertainment of the fact; and the fact of innocence is of as much consequence as the ascertainment of guilt.

It has oft-times happened in the twenty-nine years that I have been concerned with the prosecution of criminals, that I have had occasion to order dead bodies taken up on suspicion, or that suspicion might be removed. There is a case reported by that very accurate and excellent officer, now deceased, William H. Taylor, of New Bedford, whom you may remember, where he caused the body of a woman to be exhumed after having been buried forty days. He had the stomach taken out, and the proper processes set in motion to ascertain whether an abortion had been committed. There had been spread abroad a suspicion that the woman had been poisoned. This could not be traced to definite sources; but the suspicions gained credence, as such rumors do, till he performed his duty of holding an autopsy, and he ascertained that the suspicions were unfounded.

Come back, then, to the elucidation of the expression, "supposed to have come to their death by violence," and answer the question, "Supposed by whom?" I repeat the answer I made before, Every man who has a reasonable ground of supposing that the death is the result of violence has the right, and it is his duty, to communicate that suspicion to the medical examiner, and if he finds upon inquiry that it is honestly obtained, there should be an investigation to determine the truth. I conceive that it is the duty of the medical examiner not to consider whether he shall impose a cost of four dollars and travelling expenses upon the county, but to resolve the doubt; and if he has resolved the doubt in favor of innocence, he has earned the money, and the Commonwealth or county can well spend that sum to have that suspicion allayed.

I am told that there is some hesitation on the part of some of your body as to how far they should proceed upon rumors; how far they should yield to the solicitation of those whose imaginations are inflamed by baseless suppositions. Bear in mind, gentlemen, that like all other remedial laws put into the hands of officers employed by the State to make the law, a great deal is necessarily entrusted to the sound discretion of those charged with its execution. This is why men of learning and experience are selected for that purpose. No one can lay down rules; the medical examiner must be uninfluenced by considerations of the county treasury, or by the objections of county officers against the expense, but by considerations which are founded upon his own good sense and experience. Bear in mind that the resolution of any doubt is far cheaper in the long run for the county and the Commonwealth than the expense of the view.

Then, assuming that he has been told — it need not be his own suspicion necessarily — that there are well-grounded suspicions on the part of any person that the death was by violence, the statute proceeds to lay down his duty. If it is within his district (and of

course I cannot say that a medical examiner will go out of his district, but he will not refuse when time requires immediate action), two things are before him, which are successive in their nature, either one of which, or both of which, may lead him to the next step—that is, to ask for authority to hold an autopsy. The first is the “view”; and I may be permitted later to give some special suggestions about the view. Second, a “personal inquiry,” which is not evidence, of course, but is of great importance in leading the medical examiner himself to a sound conclusion. And then, third, when, in his judgment it is necessary for complete satisfaction of the question whether there is guilt or innocence, the holding of an autopsy on the authority of the town officers or the district attorney. All these means are before him. Charged with the duty of ascertaining definitely the innocence, or, on the other hand, definitely getting a belief in violence (meaning by that expression “unlawful act of another”), he first views, then makes his personal inquiry, and then, if not satisfied (much more if he is satisfied of the fact of violence), the autopsy, to complete the investigation and have the evidence before him.

When he has made the report, either upon the view or personal inquiry alone, or upon the view and the personal inquiry and autopsy, that there either is no crime, or, on the other hand, that there is reason to believe there was “death by violence,” his duty is discharged, his part of the duty is concluded.

I said just now, and perhaps I did not make myself well understood, that if upon the view and personal inquiry, the medical examiner is satisfied there was death by violence, it is much more his duty to hold an autopsy. The reason I say that is because then, upon that contingency, comes in another proposition, that is the ascertaining of all possible evidence upon the subject. That leads to another branch of the duty of the medical examiner: the first is to answer the question of innocence or probable guilt; secondly, in case of the probability of guilt to obtain every possible fact that in any way bears upon the probable guilt. Of course the autopsy is the first and most obvious. Upon these questions it is impossible to assist one who is deficient by nature, and needless to teach one who is bright by the same divine gift. If a man is stupid, he cannot get the evidence. If he is bright, I cannot help him any. There are some gifted with the power of observation. I knew a man once who was specially employed in the prosecution of persons charged with “an unlawful selling of intoxicating liquor.” He was called as a witness. I saw him a good many times upon the stand as a witness; and I ascertained that what made him a good witness was not faculty of language, but it was the ability of going into the liquor saloon or any other place, where he was charged with the observation of men, and afterwards telling everything there. It is the power of observation, a gift, an instinct. I don’t know what can be done for one who has not that power. Frequently some officers will go into a place and be unable to tell what they saw; others tell everything. One is a good witness, and the other is not. Punishment of crime depends upon getting every possible fact that has to do with it; and medical examiners should understand that they have the first and best opportunity to get the facts bearing upon that question in a case of homicide.

I may be permitted again to refer by way of illus-

tration—and I would not do it if he were now living, but he was my friend, and I am present now and he is gone—to refer to that case I have already alluded to. It was the Besse case, in Marion. It was where a man was found dead, shot through the head. An ordinary man would say that’s about all there was to it. That, you would say, was the whole of it—shot through the head, where several buckshot had gone through and come out on the other side, and that was all there was of it. But read his report—what he saw when he got the peddler’s cart in his possession. Every detail. It is astonishing how everything in relation to that wagon, the wheels, the mud of the wagon, the condition of the road where it travelled—all these details turned out to be of the utmost importance. The “view” is well done when it “views” everything.

The point I am trying to make is—and this is very likely a truism to most of you—that no man, not even the prosecuting officer, can tell in advance what is going to be important and what is not. And absolutely the only way to know is to appreciate and report and record everything—everything. For no man knows when any given fact may be important.

The same thing is true of the personal inquiry, although that is of no value as subsequent evidence in the trial of the case, for it is only for the satisfaction of the medical examiner himself. It cannot be used.

But when it comes to the autopsy—I venture upon ground which I travel upon with a great deal of timidity, for I am well aware that most of the gentlemen to whom I am talking know better about that phase of it than I do, but I will venture this at least, it is not only the object of an autopsy to ascertain the cause of death, but also to exclude every other hypothesis of death. In the case I quoted, of the man shot—shot through the head by buckshot, which went in at one side and came out at the other—it looks as though that were enough. But no man can tell beforehand how important it may be to show that he didn’t die of poison, or consumption, or derangement of the liver, or from some other disease. An autopsy is only satisfactory when it examines every vital organ, and is able to report negatively on all points but the one in question.

After you have got through with your report, it is, of course, then the duty of the medical examiner—I think it is not in the statute, but it is the obvious duty of the medical examiner—to assist the prosecution by furnishing to him, or to the grand jury, or the jury, the facts he has ascertained. That duty divides itself into two parts: one is the testifying to the facts. Every medical examiner, I need not say, will from the beginning, from the very beginning, put in writing everything he sees and finds, and have it where he can get it, for no man can remember these details.

And I repeat what I have said before, that the ascertainment of the facts, without any previous theory, without feeling, simply the facts that bear upon any given way of the homicide, that bear upon innocence, is most important. When every fact is taken, seen, recorded, and is testified to for delivery, that part of the duty is done.

I touch with more reluctance upon the other part of the duty of the medical examiner, for it is this perhaps which has been a subject of more reproach to the profession than any other department of the work, and that is giving sworn testimony, or evidence, com-

mously called "expert testimony." Perhaps I cannot better present my views than to say that I know a medical man whom I have often had occasion to employ, whose name, of course, I would not now mention, but who has achieved that reputation for absolute truth, that I have known about cases where he is called as a witness and not any one is called on the other side. Both sides have had such entire confidence in the absolute accuracy and honesty of judgment that I have not found a case where anybody has been called against him. Why? Not for his superior knowledge, but because the force of conviction upon all whom he comes in contact with is that he has not worked out a theory, but has only worked for the honest truth. The defect of expert testimony, I think, is less with medical examiners to-day than with those other departments of skill and learning; with those who testify to the value of real estate and matters of that kind; the defect of expert testimony is the almost inevitable and often unconscious tendency of experts to help the side that calls them. I say it is inevitable and unconscious. Both of these adjectives I use with design, for they do very much to relieve him of the imputation of blame which might otherwise be brought against the expert. The whole duty of the officer of the Commonwealth, charged with the detection and punishment of crime, is to arrive at the truth, and when that standard is set up — "the truth, the whole truth, and nothing but the truth" as to your work — the results are the best attainable.

I have gone over in a very informal way those things that occur to me with reference to the duties of the medical examiners. I did intend to say one thing, and it is perhaps the only matter of detail I should refer to. I see it has been better said in some of the addresses of previous speakers in years gone by, and that is the importance of having the evidence where there is not any difficulty in getting at it. One of the most zealous, and in many respects ablest, of medical examiners that I have had to do with, was on one occasion so unwise — he will never be again — as to entrust the stomach of the person found dead to an express messenger to be carried to the chemist, and when it became necessary to prove that the stomach subject to analysis was precisely the same stomach taken from the dead body, the testimony of a dozen people who had handled the box was absolutely necessary. It was done without thought of the result; and it has not in my opinion marred the excellent record otherwise of that examiner. It is necessary that the evidence should be where it is certainly sure all the time. You understand that when you come to try a murder case, every essential fact must be proved beyond reasonable doubt. That is why I said that it is necessary to exclude every other hypothesis of a death, although the cause of death may be perfectly apparent on inspection. A counsel will suggest this or that hypothesis, and it is necessary to be prepared to show that the facts you have ascertained by the examination and autopsy are consistent with the conclusion you have here, and all are inconsistent with any other conclusion, and that there are no other facts consistent with any other theory.

ANTITOXIN IN LOUISIANA. — The Louisiana State Board of Health has announced that it will supply anti-diphtheritic serum to poor patients free of cost.

ON THE IODINE TEST FOR SEMEN.¹

BY WYATT JOHNSTON, M.D., MONTREAL, CANADA,

Physician to the Coroner's Court, Montreal; Lecturer on Preventive Medicine and Medico-Legal Pathology, McGill University; Associate Member of the Massachusetts Medico-Legal Society.

If one were asked to instance a couple of medico-legal tests generally conceded to be sufficiently reliable to be accepted without hesitation as a positive proof of the condition they were presumed to indicate, one would not be unlikely to select as examples the hemin test in the case of blood stains and the recognition of spermatozoa in stains due to semen as fulfilling these requirements, when properly performed by competent persons.

While this is no doubt true, it has long been recognized that the technique at our disposal for the examination of spots supposed to consist of semen leaves very much to be desired.

It is by no means certain that all the stains sworn to from time to time as being seminal have really been such, so much does the testimony concerning these objects depend on the degree to which caution and experience have tempered the personal skill and acuteness of the expert. The identification of spermatozoa with absolute certainty, while easy enough in a fresh stain, becomes increasingly difficult with the lapse of time; and the incidental handling, washing or wearing of the articles of clothing, which commonly require this examination, makes it more and more problematical whether the spermatozoa can be demonstrated entire and intact.

There are numerous extraneous objects which are so like the detached heads and tails of spermatozoa as to mislead even those who are thoroughly experienced in the work. The generally accepted rule is that no body which simply resembles the head or tail of a spermatozoon should be considered as serious proof, and the search must be continued until perfectly formed and entire spermatozoa are recognized. The uncertainty produced by finding substances resembling these heads and tails in the specimens examined, may, however, lead the expert to prolong needlessly the examination of stains which are not seminal at all. Delays from this cause may have serious results in judicial procedure, simply by retarding or preventing the public exoneration of innocent persons wrongly suspected. We have also, on the other hand, the possible miscarriage of justice owing to the experts or juries attaching importance to incomplete proof, where the other circumstances of the case are such as to arouse strong suspicions, and must not lose sight of the consequences of abandoning a search for spermatozoa because they could not be promptly found.

Thus, in addition to a possibility which cannot be altogether ignored that the bodies affirmed to be spermatozoa were not so in reality, we have the serious drawback that the expert can only feel perfectly certain that the stain is non-seminal after making protracted and laborious observations; these if omitted, may leave a crime unpunished in the case of genuine stain not received in good condition.

The difficulties mentioned do not imply by any means that the spermatozoa test is not a good one, but simply that it is not adequate for the task it has

¹ Read before the Massachusetts Medico-Legal Society, October 3, 1896.

had to fulfil of being the sole and only recognized test for semen. What is evidently wanted is some simple, prompt, preliminary test, by which one could decide in a few minutes whether a given stain is likely to repay a search microscopically for spermatozoa, or not. At the same time such a test would evidently be still more useful if it was sufficiently accurate and distinctive to afford good corroborative evidence of the presence of semen, and so to guard against the possibility of the expert being led to regard as spermatozoa some entirely extraneous substances.

A test which appears in great part to fill those conditions has recently been announced by A. Florence, of Lyons, whose monograph entitled "*Du Sperme et des Taches de Sperme en Médecine Legale*,"² contains much besides that is of interest.³

Florence recommends the use of a reagent not infrequently employed for testing alkaloids, known as the ter-iodide or tri-iodide, of potassium. This reagent is a solution of iodine and potassium iodide, in proportions which correspond to the formula KI_3 , but which is not a definite chemical combination. The formula recommended is as follows:

Iodide of potassium C. P.	1.65 grammes
Iodine	2.54 grammes
Distilled water	30 c. c.

Good results can also be obtained by one-half the amount of iodine (1.27 grammes equivalent to KI_3), but the iodine must be in excess. The well-known Gram's solution is not suitable for the reaction. The solution keeps perfectly well in glass-stoppered bottles. It should be used cold, as warmth interferes with the reaction.

When a drop of the liquid obtained by moistening a seminal stain is placed alongside a drop of the above solution on a glass slide or watch-glass, so that the edges of the drops come in contact, there appear almost immediately large numbers of peculiar, brownish-red, pointed crystals. These are rhomboidal, and resemble so closely in form, size and color the hemin crystals that they could readily be mistaken for them, though a careful examination shows points of difference. This comparison to hemin crystals will convey a better idea of their appearance than could be given by the most elaborate descriptions, and will enable them to be distinguished from the crystals which are met with in seminal fluids. They also form small turnstile groups or crosses, in the manner which characterizes the hemin crystals.

According to Florence (and my own observations confirm his statement), the crystals are sparingly soluble in cold water and very soluble in warm water, reappearing again on cooling. On exposure to the air, they gradually disappear, but reappear on adding a fresh quantity of the reagent. They are readily soluble in ether, alcohol, acids, fixed alkalies and iodide of potassium; they resist solution in very weak ammonia solutions. For their formation to be typical and abundant considerable dilution is necessary, and I have found the degree of this solution a most important detail in making the test.

Dried stains usually give the reaction in a manner fully as prompt and typical as fresh semen, and I have been using as a demonstration specimen for class use a stain on cotton over twelve months old, obtained from a homicide case. Recently, the crystals have

been more difficult to obtain in abundance, the reason being apparently the increased difficulty of obtaining a solution of the semen rather than an impairment of the reaction.

The exact nature of the crystals has not been shown, as far as I am aware; I have regarded them as some special crystalline form of iodine.

The nature of the substance which occasions the reaction has not yet been thoroughly established. Florence claims to have isolated from seminal stains a substance which he terms *viriespermine*, and which he regards as a distinctive body producing this phenomenon. He states that it does not correspond in reactions with the substance isolated and called *spermine* by Poehl. It is said to be very soluble and to resist completely the effects of ammoniacal decomposition.

By using a larger quantity of material, the reaction can be obtained in the test-tube, an abundant red or chocolate-brown deposit of crystals being thrown down. In this way the demonstration of the seminal character of a stain might even be made without the use of a microscope.

A single fibre teased out of a thread in a piece of cotton stained by semen is sufficient to give a profuse crop of crystals under the microscope.

As to the degree to which this reaction is characteristic of semen; Florence claims that it will not react with any of the other secretions of the body, such as blood, urine, sweat, saliva, tears, bile or milk, nor with pus or nasal or vaginal mucus. The secretion of the Cowper's glands does not give it. I have made a number of tests with the various substances mentioned above, and have always obtained negative results, or at all events have never obtained a characteristic reaction.

The sperm of animals is stated by Florence not to give the reaction, as far as his observations went, though these were not extensive. Personally, I have not tested this point with sufficient thoroughness to give an opinion; but as far as my observations go a pseudo-reaction of doubtful nature can be obtained with at least some forms of animal semen. This point is still, as far as I know, unsettled.

In respect to Florence's claim to priority, I think it can hardly be disputed. I can find no recent work on legal medicine in which any chemical test is given for semen. Wood⁴ says "There are no chemical tests by which seminal stains can be recognized." Dixon Mann (1893), Strassman (1895), Vibert (1896, 4th Edition), Hoffman, Taylor, Liman and our other standard authors do not refer to it. Roussin indeed recommended for examining seminal stains the use of solution of iodine and iodide of potassium, but only for the purpose of staining the spermatozoa, and the fluid which he recommended (iodine 1, iodide of potassium 4, water 100) does not give the Florence reaction. Apart from Florence's work there is practically no literature on the subject except the older work of Orfila as to the odors obtained upon heating the stains or treating them with nitric acid.

Florence states that he started with the firm conviction that so unusual a fluid as semen, which had such well-marked physical peculiarities, must contain some characteristic chemical substance. Acting with this hypothesis in view he proceeded *seriatim* to test seminal stains with all the ordinary reagents used in obtaining chemical reactions, especially those found of

² Archives d'Anthropologie Criminelle, January, February and March, 1896.

³ It has also been published separately by Storek, Lyons.

⁴ Vol. II of Witthaus and Becker's Handbook, 1894, p. 79.

value for recognizing alkaloids and those generally employed in physiological chemistry. By trying these one after the other he discovered several which gave him positive results, and among these he selected the ter-iodide of potassium as the one best adapted for medico-legal requirements.

During the past three months I have been making some observations on cadavers (22 cases) upon the occurrence of this reaction in connection with the secretions from the prostate, seminal vesicles, testicle substance and the post-mortem ejaculations from the meatus, with a view of determining whether the prostatic ingredients of the semen or the semen proper was chiefly concerned in giving the reaction. The material was obtained for the most part by allowing it to dry on cotton-wool swabs, so as to obtain a condition comparable with those under which seminal stains ordinarily come under medico-legal examination.

Pressure of other work has prevented me making these examinations with sufficient thoroughness to make their publication in detail seem advisable until I have gone over the material again more carefully, but the general results are as follows: Drying does not appear to interfere with the reaction materially within the time limits I have mentioned; and, in fact, I have often obtained the reaction more satisfactorily from moistening the dried secretion than from the original fluid. Decomposition, such as is met with in drowned bodies and bodies long exposed to the air, appeared to interfere with it to some extent, contrary to what Florence's observations would lead us to expect. The semen from the meatus or from seminal stains gave a better reaction than that substance obtained from the regions where the prostatic and testicular components of the semen had not yet mingled. Semen expressed from the prostatic duct into the urethra gave prompt and characteristic results, while these were much harder to obtain from the testes or the contents of the vesicles. So much was this the case that at first I thought the reaction might be due to the prostatic element of the secretion and not to the strictly seminal part. In some cases, however, typical results were obtained from the contents of the seminal vesicles and from the substance of the testicles. In two cases the reaction was imperfect or almost absent, certainly not sufficiently typical to justify medico-legal deductions, one being a case of cancer of the seminal vesicles and prostate, and the other double chronic vesiculitis with corpora amylacea very abundant in the prostate. In both of these spermatozoa were present in the semen.

Hypertrophy of the prostate did not appear to affect the reaction. In one case the reaction appeared to be present before the period of puberty (seven and one-half years), though here it did not appear to be perfectly typical and satisfactory. I could not find it in the secretions of infants and very young children.

These few observations are not so much recorded here with a view of passing judgment upon the percentage reliability of the test as to indicate the direction in which observations might be made, as the total number of observations I have been able to make so far is not sufficient to justify general conclusions.⁵

With regard to the practical merits of the test,

I think that those who use it for testing seminal stains will agree as to its decided value as a preliminary test, and accord it a position analogous to the guaiacum test for the blood, by which we can promptly find out whether there is a probability of positive results being obtained upon further examination. Personally, if it was obtained in a typical manner, I should regard it as very strong corroborative evidence in a case where spermatozoa were claimed to be present.

With regard to its independent value as a test, Florence formulates his conclusions as follows:

(1) From the occurrence of the reaction alone, without discovering even fragments of spermatozoa, he would conclude that it was probably a seminal stain.

(2) From the coincidence of well-formed and typical but detached heads of the spermatozoa, along with the reaction, he would affirm positively the presence of semen.

(3) With *débris* of spermatozoa or even with perfectly-formed heads, but without the reaction, he would not feel certain that he was dealing with a stain produced by human semen.

It will be noticed that Florence attaches to the detached heads of spermatozoa more significance than is accorded to them by our standard authorities. It must be mentioned that Florence has added materially to the data which may be used in identifying the heads of human spermatozoa, as the result of his careful study by means of oil immersion lenses and staining methods. By these more refined methods, highly characteristic details were brought out which would escape notice if ordinary dry lenses of moderate magnification were the only ones employed. The illustrations of spermatozoa given in his monograph are far superior to the illustrations which adorn the average medico-legal text-book, which are in many cases little more than caricatures. It must be remembered that the drying and subsequent moistening of the spermatozoa have a tendency to deform them somewhat, so that the appearance obtained may not always be perfectly uniform. This tendency to deviation would, however, be more likely to cause human semen to be confounded with that of animals, than the reverse. Personally, my experience does not entitle me to express an opinion as to the extent to which detached heads and tails of spermatozoa should be allowed to constitute evidence of semen, but I think it will be a long time before anything less than the entire spermatozoon will be accepted as legal tender by either judges or juries.

I think it can be said with confidence that the iodine reaction of semen, as described by Florence, is a decided step in advance, and that in it we have a new and very promising preliminary and confirmatory test for normal semen, and one which gives relatively good results in the case of stains which from a prolonged drying, react with difficulty to the microscopic test.

The sources of fallacy which attend the iodine test are, however, as yet practically unknown.

To determine what inference may be drawn from the absence of this reaction in a suspected stain, we need much fuller information and experiments on the effects of external conditions, etc., upon substances known to be stained by semen; we also need information as to the extent to which pathological conditions may exert a modifying influence, how the age limit affects the reaction, and on many other points.

⁵ Two instances of advanced and well-marked disease of the seminal receptacles is obviously a very high proportion for only 22 cases. In both these two instances of organic disease the fact of iodine reaction being interfered with while the spermatozoa were still present indicates the greater certainty of the spermatozoon test.

Before we can assign accurately the significance of a positive result, we require much further testing and corroboration regarding the behavior of the reagent with substances other than semen, and also with the semen of animals.

After making all due allowance for this we must rejoice at the success of M. Florence in discovering a crystalline reaction for semen. As a rule, a good crystalline is better than a color reaction and we may expect that further researches in this direction will lead to the discovery of new and valuable micro-chemical tests.

A REPORT OF THREE DEATHS FROM HEAD INJURY.¹

BY FREDERICK H. BAKER, WORCESTER, MASS.,
Medical Examiner.

THESE three cases are reported to the Society, not on account of their rarity but rather for the reason that each has certain interesting and practical peculiarities, and still more for the reason that they collectively illustrate anew the well-known fact, that fatal violence may be applied wilfully or otherwise to the head leaving externally little or no evidence of the intracranial damage which it has accomplished.

Medical examiners are not infrequently called to act upon cases of this character where the objective evidence is very slight, and where, for obvious reasons, a truthful history is not given, and it is only by most rigid examinations and often by autopsy alone that we escape falling into grievous error.

CASE I. I was summoned by the Police Department about 1 A. M., November 13, 1895, to investigate the cause of death of a young man, H. E. D., who had died suddenly upon the floor of a dance-hall a short time before my notification. Upon my arrival I found a number of young men present around the body, all of whom could tell how he was picked up apparently in a faint, and carried to the window for air; but as to the cause of his being on the floor they claimed to be entirely ignorant. They freely advanced several theories as to the cause of death, such as "heart disease," "a fit," and the "bursting of a blood-vessel in the head"; but all denied that there had been any quarrel.

Upon examining the body two things only were noticeable: marked pallor, and a slight swelling beneath the left eye, which his friends declared he received when he fell upon the floor; but a careful examination did not show any contusion or injury of the scalp.

Shortly afterwards it became known to the police that there had been trouble between the young man who lost his life and another young man named J. O'S., the quarrel starting from their pushing each other in their eagerness to reach the coat-room. They had been strangers up to this time; but after a few hot words they stepped out into the dance-hall, sparred a moment, when O'S. struck D. below the left eye, and when the latter bent over to seize his opponent by the legs he was dealt another blow just above the left ear. He sank to the floor, dying in a few moments without regaining consciousness. Neither had been drinking.

The body was ordered to be removed to the City

Hospital morgue, where I performed an autopsy about twelve hours after death.

Autopsy.—The body was that of an exceedingly well-built young man, aged eighteen, height five feet and nine inches, weighing about 160 pounds. Rigor mortis was present throughout the body. Pupils dilated eight millimetres, and equal. The discoloration about the eye was much more marked than at the time of the first examination. Upon taking off the scalp, which was perfectly normal, there was found a contusion of the left temporal muscle, there being a rupture of its fibres with an infiltration of semi-clotted blood over an area about the size of a cent, one inch directly above the external auditory meatus, apparently made by the knuckle of his antagonist. The skull was of normal thickness. There was no extradural hemorrhage, and the dura itself was normal; and on being removed two or three ounces of very reddish fluid (blood and cerebro-spinal fluid) escaped, and a thin clot of blood was seen spreading over the lateral surfaces of both hemispheres, dipping between the convolutions, especially over the motor areas, and extending downward toward the base, where a large fresh clot lay over the Pons Varolii. There were also numerous small areas of extravasated blood in the pia mater and subarachnoid tissue, away from the areas covered by the thin clot. It was not possible to find the vessels which had been ruptured, nor macroscopically was there any laceration of the brain tissue. There was no rupture of the venous sinuses or fracture of the skull, nor did the blood-vessels show any signs of disease. The brain substance and the ventricles were normal. The other organs of the body were normal.

Following my routine custom in all autopsies, cultures were taken from all the internal organs; but, as was to be expected in this case, with negative results.

The interesting facts in this case are (1) the suddenness of death, (2) that a strong, athletic young man should be killed by one or two blows given by a man of less than average strength and having no knowledge whatever of boxing, (3) that the blow which was probably the fatal one (the one over the ear), left no mark externally. C. O'S. was arrested and indicted for manslaughter by the grand jury. As it had been ascertained that the deceased was the aggressor, and that there were many extenuating facts in favor of the defendant, he was allowed his freedom on probation.

CASE II. This man, A. J., died as the result of a faction fight in the street between Swedes and Finns on the outskirts of Worcester on the evening of December 2, 1895. Parties of both nationalities were in a saloon drinking when the quarrel started. Reinforcements were wanted, and the victim was summoned from his house near by; and he had not been at the scene of the row, which was transferred to the street, more than two minutes when he was struck in the head by a stone thrown by some one in the crowd. Later, at an inquest, evidence was given that showers of stones were thrown in the darkness by both sides; and it is doubtful if the man who threw the fatal stone was aware where it struck. The injured man walked back to his house and complained of severe pain in his head.

However, he went to his work the following day; but the pain growing more severe, he was obliged to quit work. The pain grew worse. A physician was

¹ Read before the Massachusetts Medico-Legal Society, October 3, 1896.

called, who examined his head carefully, but did not find a mark of any kind upon the scalp, or any objective signs of fracture. Four days later he became so wildly delirious that he required restraint, and was sent to the hospital, where he died the following day with all the symptoms of meningitis.

Autopsy, twelve hours after death. — A Finn, height five feet and nine inches, weight about 180 pounds. Rigor mortis very marked throughout the body. Another careful search failed to show any external mark of violence about the head. Upon removal of the scalp I found a condition almost identical with that of Case I, namely, a normal scalp with a contusion of the right temporal muscle over an area of the size of a fifty-cent piece. Directly beneath this was found a linear fracture through the entire thickness of the skull, without any depression, starting two and one-half inches directly above the external auditory meatus, running downward through the middle fossa, and ending in the petrous portion of the temporal bone in the external auditory canal, in which was found a small clot of blood. The dura was not ruptured, and appeared nearly normal. The brain revealed a most intense general purulent leptomeningitis, so marked over the area of brain around the seat of fracture as to conceal completely the gyri, which were everywhere flattened. The meningitis was particularly marked also at the base of the brain. The ventricles were slightly distended with a purulent fluid which was not bloody. The brain substance was very slightly lacerated, only at the point near the middle of the fracture. The corresponding part of the brain on the opposite side did not, macroscopically, show any evidence of laceration or contusion, nor did thin sections of the brain disclose any minute hemorrhages or other alterations. The only variation of the internal organs from the normal was what might be found in any case which had had a high temperature for a number of days. I made at the time of the autopsy cover-slip preparations from the purulent exudate to determine the nature of the infection, and found only one organism present, namely, the micrococcus lanceolatus. Cultures were taken from the various internal organs; but they remained sterile, showing that the infection was not a general one.

This case has certain peculiarities: (1) That a stone thrown with sufficient violence to fracture the skull through the base and lacerate the brain substance should leave no external mark of violence; (2) That a man should be able to work with so severe an injury.

Numerous arrests followed his death; but from the nature of the fight and the number involved, and the fact of the darkness at the time, there was not found evidence enough to hold any one for homicide.

CASE III. This case is reported with the permission of the district attorney. On Sunday morning, September 13th, I was called to the Worcester City Hospital, in my capacity as pathologist to that institution, to perform an autopsy upon a woman, A. H., who had died there the previous evening. Briefly the history given was that she had been drinking heavily the past few weeks, and, being ill, a physician had been called four days before her entrance, who sent her to the hospital as a case suffering from alcoholism. She was able to ride to the hospital sitting up in a hack, but appeared stupid. She had no paralysis whatever, and shortly after entrance she articulated perfectly in

answer to inquiries. She got out of bed and stood up for a moment the day before she died. A few hours before death she became unconscious; her pulse became very weak, and Cheyne-Stokes respiration developed, this condition remaining to the end. The scalp wound was dressed antiseptically while in the hospital; but its apparently insignificant character and the fact that she had no paralysis led to the belief that the cerebral symptoms were due to alcoholism.

Autopsy, twelve hours after death. — A well-developed woman, aged thirty-eight years. Rigor mortis present. The only mark of violence about the body was a small lacerated scalp-wound about one half-inch in diameter and one and one-quarter inches above the external auditory meatus: the whole wound was slightly suppurating. Upon taking off the scalp it was found that the left temporal muscle beneath the scalp-wound was perforated, and it was also found that directly beneath this was a clean-cut circular hole in the temporal bone nine millimetres in diameter. There were lacerations in the dura mater at this point, one hole being about as large as the perforation in the bone, the other a small one near it produced by a spicule of bone. The skull was slightly thinner than normal, but not remarkably so. The inner table of the temporal bone was shattered and imbedded in the brain. At first sight, it suggested strongly a bullet-wound. There was a slight amount of clotted blood outside and beneath the dura at the point of injury, but not so much as would be expected. The brain was punctured opposite the tear in the dura, and there was marked flattening of the convolutions over the whole left side. Just how far the brain was pierced could not be determined, as a cavity was found in the subcortical brain substance, beneath the point of perforation, about the size and shape of a lemon, extending into the frontal lobe. It was filled with clotted blood and yellow, softened brain-tissue. The meninges were markedly engorged with blood, but there was no evidence of supuration. The other organs of the body were of normal appearance. Cultures from the organs were negative.

Upon finding these conditions at the autopsy I immediately communicated with the chief of police, who detailed detectives to investigate the case. This resulted in the arrest of the husband and a brother of the deceased. The brother confessed that one week before her death he had, during a wordy quarrel, struck his sister by making a lunge at her with an umbrella. The umbrella was obtained, and found to have a metal tip which exactly fitted the hole in the skull. The brother apparently did not realize the extent of the injury at the time, nor did the injured woman, who ran down stairs, and was not confined to her bed until the following day.

This case is one where the absence of characteristic clinical symptoms of intracranial injury and the placing of too great reliance on the history given led naturally to diagnosing the case as alcoholism. It was only from the fact that the husband gave permission to have an autopsy that led to the discovery of the real cause of death and the arrest of the assailant. He was subsequently sentenced to the House of Correction for the term of one year.

JAPAN is said to contain a greater number of thermal springs than any other country on the globe.

FIG. 2.
Double-stained Spermatozoa, from a spot on cloth
eight months old.

THE IDENTIFICATION OF SEMINAL STAINS.¹

BY W. F. WHITNEY, M.D., BOSTON.

At the last meeting of the Society a paper was presented by Dr. Wyatt Johnston describing a microchemical test for seminal stains proposed by Florence, of Lyons. It is briefly as follows: A suspected spot is soaked in distilled water for a few minutes, and to the fluid obtained is added a drop of a saturated solution of iodine in iodide of potash (iodine, 1.65; iodide of potash, 2.54; water, 30). An immediate precipitation of dark-brown rhombic crystals of iodine takes place. Their general shape and appearance very closely resemble those of the so-called hemin crystals, which are obtained from blood stains by Teichman's test. (Fig. 1.)

FIG. 1.

Crystals obtained by Florence's reagent, from a spot on cloth eight months old.

The reagent and material were placed in my hands for confirmation of the statements made in regard to them. I have gone carefully over the ground, and find the facts to be, in every particular, as stated.

The reaction took place readily both with the material furnished by Dr. Johnston, and that which was prepared under my own direction. The only difficulty encountered was that it was found impossible to dissolve all of the iodine according to the given formula. But after taking up as much as possible the filtrate was found to act perfectly.

Crystals were readily obtained from stains, which had been dried for a few days, several months, and two and a half years.

Stains from any other of the ordinary fluids, etc., of the body (urine, saliva, milk, fecal material), failed to give the reaction, as well as from leucorrheal and gonorrheal discharges.

Trials were also made from the contents of human testicles, epididymis, and seminal vesicles without any result; except in one recently excised testicle a few small crystals were thrown down by the fluid squeezed from the epididymis. The fluid from a spermatocele containing large numbers of spermatozoa was also negative. The fluid expressed from the prostate was without action, both when used alone or mixed with

the secretion from the seminal vesicles. Of course, with the exception of the testicles, the material came from the autopsy table, and post-mortem changes cannot be ruled out. But the evidence from all of the available material shows that as far as man is concerned the peculiar substance which gives the reaction is formed in the mixed seminal secretion during life.

From the epididymis of a rabbit, however, an abundant precipitation of small crystals was obtained; while from that of a dog there was no result.

A preparation was made from a spleen from a case of leucemia, in which were numerous Charcot-Leyden crystals, which are regarded as identical in composition with those formed in slowly evaporated semen. The result of the test was negative.

I can throw but little additional light upon the nature of this peculiar substance; and its isolation must be left to the chemists.

But it is certain that the test will be of great value in preliminary examinations for medico-legal purposes, and one that should never be omitted in the examination of suspected spots.

As the reagent gives a precipitate with many of the alkaloids (morphine, strychnia, etc.) and their salts, its chief value is a negative one, just as is the guaiacum test for blood stains. So that if a positive result is obtained the further step of demonstrating the presence of spermatozoa must be taken before it can be submitted as evidence in court. For this end, I have made a series of studies to improve the technique and so facilitate such examinations. And the following is the best method which I have found, thus far:

A small bit is cut from the cloth on which is the suspected spot, or if it is on a hard surface a little is scraped from it. This is placed on a cover-glass, wet with a drop of distilled water, in which it is carefully teased apart with fine needles and the larger fibres removed. The drop of fluid is carefully evaporated over a flame and fixed to the surface by rapidly passing it through it three times. Upon the film thus formed, are poured a few drops of an aqueous solution of eosine, which is allowed to act for a few seconds and then washed off with distilled water. An equal amount of a strong aqueous solution of methyl green is then poured on and gently heated over the flame until it steams. It is again washed, dried and mounted on a drop of Canada balsam dissolved in xylol. The preparation thus obtained is permanent, can be examined with the highest powers of the microscope, and exhibited in court, if necessary.

When entire, well-preserved spermatozoa are found there is no difficulty in their identification. But when the stains have been dried for some time, it is usually difficult to obtain such ones, for the heads are then very easily broken off from the tails. And in an unstained preparation, the former can easily be mistaken for spores, or *vice versa*, and the tails are almost invisible from their smallness and transparency. With the method above given, certain differential characters of the head can be made out which leaves no doubt as to their identity. Its composition is stated in the books to be of the same character as the nucleus of a cell (chromatin) and stains with the same reagents. But an examination of Fig. 2, will show that the whole head does not stain alike. At the base is a hemispherical portion which stains of deep green, while the anterior part and the tail takes the red color of the eosine. This serves at once to identify it, as

¹ Read before the Massachusetts Medico-Legal Society, February 3, 1897.

there is no other oval spore or cell which has an eccentric hemispherical nucleus.

And, furthermore, this not only shows that they are spermatozoa, but also that they are from man. For in no other animal is there a deep staining. For in all the others, the head stains of a very diffuse light green, with only a very narrow zone of a pale red color about it. Then, too, the shape of the head is different, being more pointed in man (wedge- or lance-shaped), while it is rounder (shovel-shaped) in the lower animals. Those of the dog are most like the human, both in shape and details of staining; but a little experience will show differences quite plainly.

With this method, stains varying from a few days to two and a half years old were examined, and in all the differentiation of staining was preserved, and the identification could be easily made.

From the above it is evident that with Florence's test and the double staining of the spermatozoa, there should be no doubt in the mind of the medical examiner of the presence or absence of semen in a suspected spot.

ON THE DUTIES OF A MEDICAL EXAMINER AS A WITNESS.¹

BY SHERMAN HOAR,
United States District Attorney.

MR. PRESIDENT AND GENTLEMEN: When I was at Cambridge, an instructor once gave out to six members of my class the same subject upon which to write a theme, giving us opportunity to read over each other's compositions, and telling us to then make our own compositions original, if possible. Then the Instructor took our papers, and read them out aloud to the class; mine happened to be the last one. When he came to mine, he asked me to read it, and I began. As I read he said, "That is true; but Smith has already said that." And then he took up the next proposition, and said, "That is true, but Sewall has said that." And so on, one page after another, with all my propositions, until he came to my name; then he said that was the original thing in my composition. I think when I get through, the name will be the only original part of my propositions. For, like the Attorney-General, I have not been able to prepare myself for such an occasion as this.

I entirely agree with the Attorney-General that the first duty of anybody connected with the prosecution of crime is judicial; that no person can properly, either as prosecuting officer or medical examiner, or as a witness, serve on a case except as a judicial officer in the first instance; and I think that is too often lost sight of both by prosecuting attorneys and by medical examiners. I think it is very essential for everybody first to ascertain the facts and to find out exactly what is true, and then to be able to express that truth in such a way as to convince twelve men of at least ordinary intelligence.

I have had little experience with medical examiners. I have tried but one murder case in all my life, and that is all I want to. In that murder case I had a medical examiner from this district who gave evidence, and a medical examiner from Halifax who gave evidence, and the difference between the two men illustrates exactly what I want to say. One of them had

made his investigation as a judicial officer; the other had made his seemingly for his own aggrandizement. He had his own dignity to maintain; he had his own opinion to maintain. He had an absolute inability to make himself understood by any human being who listened to him.

Now you have not only to ascertain your facts judicially, to keep your mind open, to do what the Attorney-General said so well, "ascertain all the facts"; but I would like to add that not only should the medical examiner ascertain all the facts which the autopsy shows, but should be able to make twelve men selected almost at random understand what he means when he states those facts. I have heard medical experts give testimony a great many times; sometimes I have understood them, and sometimes I have not. I have heard two medical experts give testimony in the same case, one of whom I understood and the other I did not understand. And I say that a knowledge of the English language is essential, as essential as a knowledge of medical terms. You must remember that Dr. Holmes once said of a lawyer that he had to half-know more things quicker than anybody else in the community; and you have got to get your lawyer, your prosecuting attorney, to half-know what you know, and be able to draw it out of you on the instant on the witness-stand; and you have got to get him into a condition of mind, by the use of ordinary, plain, Anglo-Saxon words, to understand your exact view of the case. You have got to get him into a condition where he can draw out from you what you want to present to the jury, to the twelve men, often of very limited understanding. And if I could add anything to what the Attorney-General has said, it would be to urge the right and simple use of the English language in putting in your evidence.

When you come to testify, you are so apt to qualify your judgment that you don't give your opinion, but your qualifications first. And if I should make a suggestion to you, it would be to give your judgment first, your reasons for it next, and any limitations upon your judgment last. I think the jury would understand you better if you did that.

I should like to have medical examiners remember that they are judicial officers; that they are part of the machinery of the Commonwealth to detect crime. I don't believe that, as such judicial officers, they have a right to take sides in any case whatsoever; neither do I believe that, as such judicial officers, they have any right to take the side against the Commonwealth in any case which may be presented in the Commonwealth. I believe that they ought to always keep their minds open; to learn all the facts accurately—medical and otherwise; that they ought to keep themselves in a judicial condition of mind until the case is through; that they ought to give their opinion first, their reasons next, and qualifications of that opinion last; that they ought to try to reduce everything they say to the ordinary language of human beings who are on the jury before them.

LEAD-POISONING FROM SNUFF. — A case of poisoning from snuff adulterated with lead has been discovered in New York, and the tobacconist who sold it has been arrested for obtaining the price of the snuff upon false pretences. As snuff was not a food, he could not be held for selling adulterated food.

¹ An Address before the Massachusetts Medico-Legal Society, February 3, 1897.

Clinical Department.

UREMIA FROM ANURIA.¹

BY GEORGE HILLS FRANCIS, M.D., BROOKLINE, MASS.

THE patient was a married man of forty-seven years, about 5 feet 11 inches in height, and weighed 170 to 175 pounds. He was of particularly good health, in appearance. His family history was good, his ancestors having all died from legitimate causes. There is nothing in his early history to lead one to suspect any trouble caused by bad habits, neglect or abuse. He was born in Scotland. Some years since he married and moved to the East, living for some time in India. Hence he moved to China, and at the time of his death he was in the Customs Service and held high rank under the Emperor.

Two years or more before the present sickness, the patient had disease of his bones. He was operated on several times, for the removal of sequestra and necrosed portions which had not loosened. At the time of his death, there was a rubber drainage-tube passing through his left thigh and draining a diseased portion of the femur.

Six months or more before I first saw him, he noticed that his urine began to look thick, white and stringy, and he passed a few small calculi. He did not notice any other particular change in the water, nor did he feel any symptoms which led him to fear a grave disease. He had no pain, fever or emaciation. His appetite was good. He slept well, and did not feel that the functions of any of his organs were disarranged, although he did not feel able to do his usual amount of work. He received a furlough to travel for his health. On reaching Edinburgh he was thoroughly examined by several of the most eminent physicians connected with the University of that city, who agreed in their diagnosis that there was no sign of any disease of the kidneys, but that the urine contained considerable pus which came from the bladder.

From Edinburgh he came to New York, and there consulted Dr. Sayre, who treated him with irrigations of the bladder, making repeated examinations of the water, and assuring him that there was no kidney disease.

Following Dr. Sayre's advice he made a three weeks' trip to the vicinity of Albany. While there he felt as well as ever in his life. On Saturday, September 29th, previous to his departure for Newton, Mass., he shot two deer. He reached Newton on Monday morning October 1st, and from five o'clock on that afternoon up to the time of his death was under the almost continual observation of my father and myself.

October 1st. When first seen the patient was not feeling sick in any way, except for a slight pain in the left groin, but he had not micturated since midnight.

October 2d. There was no change in the condition. His appetite was good. A catheter was passed into the bladder without encountering any resistance. No water was obtained.

October 3d. The patient appeared perfectly comfortable except for an increase of the pain in the groin.

October 4th. Appetite almost gone. No other marked change.

October 5th. No headache, no impairment of any faculties. A report of the urinary examination before sickness was received from Dr. Sayre, which did not refer the disease above the bladder.

October 6th. The stomach begins to reject food, although some is retained. Slight attacks of hiccoughs occurred from time to time. Dr. John Homans examined the patient very thoroughly and advised against surgical interference.

October 7th. Pulse begins slowly to rise, being about 75 in the A.M., 85 in P.M. Stomach rejects all food; slight headache; hiccoughs worse, although not incessant; faculties not impaired.

October 8th. Hiccoughs almost constant. Pulse 100. There began to be muscular twitchings, especially of the hands and feet. The patient is conscious. He can take no food.

October 9th. Pulse 120. Almost constant twitching of muscles over the entire body. Slightly comatose, although easily aroused.

October 10th. Symptoms all aggravated. Movements incessant, but no marked convulsion. Semicomatose all day till three P.M., when death occurred.

At no time during his sickness was there the least moisture of the skin.

The treatment of this case was largely for the relief of symptoms. Hot-air baths and pylocarpine were used without the slightest result. In the early stages diuretics were given, but later abandoned. Morphine was given hypodermically for the relief of vomiting. Baths were given frequently, and were most acceptable to the patient.

The autopsy was performed by Dr. H. M. Cutts eighteen hours after death.

Rigor mortis, very marked. Body well nourished, although the limbs were not large. Skin discolored in scattered patches by a purpura. On opening the abdomen a layer of fat about one and one-half inches thick, was cut through. There was also a large amount of fat in the omentum and other portions of the abdomen. The peritoneum and also the intestines were thick, pale and of a pearly color. On the right side, the colon and small intestine were adherent to the abdominal wall by quite firm bands. Fluid in the cavity of abdomen was slight in quantity. There were no marked lesions in the stomach, intestine, liver, spleen or pancreas. The kidneys were surrounded by an abnormal amount of fat. They were removed from the surrounding parts with great difficulty, there being signs of severe acute inflammation especially around their upper halves. The bladder appeared to be empty. The head and thorax were not opened.

The left kidney was six and one-half inches long, four and one-half inches wide, and weighed in the neighborhood of one pound. It was lobulated, and at the prominent points fluctuated. The capsule was adherent. The surface, although reddened in places, was not far from normal.

The cavity of the pelvis contained about three-quarters of an ounce of pus, and also a triangular-shaped calculus about seven-eighths of an inch long. In the substance of the organ were five cavities, each about the size of a peach-stone, filled with pus. The pyramids were largely obliterated and the cortical portion was firm and hard. The left ureter was about normal in size.

The right kidney, on external examination, appeared very similar to the left one. This organ was

¹ Read before the Brookline Medical Club, January 12, 1897.

not opened, but was sent to Dr. R. F. Fitz, who reported the following:

"The kidneys received were extensively diseased. There was a chronic diffuse nephritis and a fresh pyelonephritis. The bladder contained apparently nothing but pus, suggesting that death was the result of uremia and suppression of secretions."

The right ureter was dammed by a calculus, the size of a large pea. Above this the calibre was three times the normal size. The bladder contained about 10 ounces of pus, which was probably forced into it while the urinary tract was being removed from the body. The walls were considerably thickened and the inner surface was somewhat congested, but the general condition was very good. No urine was found anywhere.

In discussing cases of anuria I take the liberty to quote quite freely from a paper written by Dr. John W. Farlow, which was published in the *Boston Medical and Surgical Journal* of April 4, 1889.

Cases of anuria can in a general way be divided into two classes: first, those caused by disease of the organs; second, those caused by obstruction. The first class usually die very soon after the flow of urine stops, from shock or exhaustion due to the disease. The second class is generally due to some mechanical cause, and in these the true effects of failure to secrete urine and to eliminate urea in that way are manifested. The duration of life after the entire suppression of urine is from nine to eleven days, although in some cases it is much longer. About fifty per cent. of the cases are caused by calculi. Other causes are growths of various kinds and adhesive bands caused by inflammations. A few cases are reported in which there is not an obstruction. These are due to mercurial poisoning, cystic degeneration of kidney, abscess of kidney, cholera, scarlet fever, diphtheria and hysteria. When any water is passed, it is generally pale and contains no albumin or casts. It is found that passing a very small amount prolongs life but a very short time. The urea which should be passed in the water is eliminated to some extent by the vomiting which is a very constant symptom. The skin also helps to a greater or less extent."

Charcot held the theory that the retarding of uremic symptoms is due to the slowing or enfeeblement of denutrition, "that it is like a fire covered with ashes. The processes of combustion have stopped."

Twenty-four per cent. of Dr. Farlow's cases recovered.

Medical Progress.

REPORT ON PROGRESS IN PUBLIC HYGIENE.

BY SAMUEL W. ABBOTT, M.D., BOSTON.

(Concluded from No. 13, p. 310.)

THE USE OF FORMIC ALDEHYDE GAS FOR THE DISINFECTATION OF LARGE APARTMENTS.²

RECENTLY attempts have been made to attain a more rapid and abundant evolution of the formic aldehyde than was possible by the use of formalin. This has been accomplished by the imperfect combustion of methyl-alcohol in especially constructed

lamps. The author refers to the experiments of Diendonné with a lamp made by Tollens, and later with one manufactured by Krell; and he explains that, having been entrusted by the Prussian War Minister to carry out a series of investigations into the use of this gas, he communicated with Diendonné and obtained a series of lamps in October, 1895, and in February of the present year. An explanation is given of the construction of these lamps, which had each a capacity of 200 cubic centimetres, and an account follows of their use under various conditions set forth by the author.

The three hospital rooms in which the tests were made contained respectively 9,286, 3,248 and 2,118 cubic feet; the first served for seven beds, the second for three, and the third could, if the necessity arose, be used for two beds. The furniture and all the contents remained undisturbed during the trials, and were in no case injured in any way by the formic aldehyde gas. The test objects (infectious matter) were placed about the rooms, on the tables and on the floor, in open glass vessels, and they consisted for the most part of such matters as would commonly occur in rooms which required to be disinfected, such as tuberculous sputa, both fresh and dried, and also pure cultures of typhoid, cholera, diphtheria and other bacilli, some being in the form of fresh agar-cultivations and some dried upon silk threads. To avoid a loss of the gas in consequence of the imperfect fitting of the doors and windows, certain of the chief crevices were pasted up. The vapors were allowed as a rule to stand in the rooms for twenty to twenty-one hours, though in a few instances the experiment only lasted for fifteen hours. The number of lamps used, the weight of methyl-alcohol utilized, and the effects upon the various test objects are set forth in tables. The trial of the room containing 9,286 cubic feet, for which eighteen lamps were employed, was a failure; and no results are in this case published. A maximum of eight lamps was used in the room containing 3,248 cubic feet, and 5.4 grains of methyl-alcohol per cubic foot of space were consumed; but much larger quantities were employed in some of the smaller wards in which tests were made.

Certain difficulties which arose in carrying out the process induced the author to suggest the construction of more powerful lamps in which larger volumes could be volatilized, or, as is pointed out, it would be much more convenient if the gas could be liquefied in the same way as carbonic acid and sulphurous-acid gases, and could then be conveyed into the rooms to be disinfected; but this at present does not appear possible.

As the result of his tests, the author states that he does not think this gas can be employed with useful results in the disinfection of large spaces; and in this view he is confirmed by the recently published experiments of G. Roux and A. Trillat, who were unable by the use of a Bardet-Trillat apparatus, consuming 8.8 pints of methyl-alcohol, to disinfect with success a room containing 2,754 cubic feet.

Another valuable contribution to this subject is the recent paper of Dr. Kinyoun.³ As the result of his experiments in the hygienic laboratory at Washington, Dr. Kinyoun says it is demonstrated "that the

² Prof. Dr. E. Pfuhl: *Zeitschrift für Hygiene*, 1896, vol. xxii, p. 33.

³ Formaldehyde as a Disinfecting Agent, and its Practical Application. Public Health Reports, Marine-Hospital Service, Washington, D. C., January 29, 1897.

gas is a valuable disinfectant for surfaces, and for the lighter articles, such as curtain-hangings, clothing, carpets and bed-coverings. The gas was germicidal in all save where the test cultures were tightly wrapped in many layers of the fabrics. Interiors of books were difficult to disinfect.

It is doubtful whether the interior of articles such as upholstered furniture, mattresses and pillows can always be disinfected unless a much larger percentage of gas is applied than was used in these experiments.

The main obstacle in the way of applying formaldehyde gas, or any other gaseous disinfectant for that matter, is in not being able to close the apartment sufficiently tight to prevent the escape of the larger part of the gas. In our experiments extra precaution was taken to close all avenues, and yet, notwithstanding this, there was but little gas present, in comparison, after thirty-six hours had elapsed. The only way this can be guarded against is by using an excess of the gas. Just in what proportion the excess should be, will entirely depend on the local conditions.

It occurs that the length of exposure is secondary to the amount of gas used. A large per-volume strength will accomplish the object better and in a shorter time than by the using a small amount of gas and prolonging the exposure. For room disinfection, under favorable conditions, fully twelve hours' exposure should be given. After twenty-four hours it is believed little or nothing will be accomplished.

THE EFFECT OF THE GASEOUS AÉRATION OF WATER ON BACTERIA.

The extensive use of carbonated waters has given rise to an examination of such waters with reference to the effects of carbonation upon the bacterial life of the waters thus treated.

Dr. Frankland⁴ states that widely different waters are employed in the manufacture of aerated waters, the bacterial contents of which differ widely, both qualitatively and quantitatively. Some bacteria rapidly disappear in such waters, and others are but little affected. In one instance a sample of carbonated water was found to contain, one hour after its manufacture, 8,350 microbes per cubic centimetre. These figures rose in 210 days to 212,400 per cubic centimetre; and at the end of 428 days had fallen to 46 per cubic centimetre. As regards the behavior of pathogenic bacteria in carbonated waters the results are more decidedly unanimous; and the general impression that a barrier of no mean obstructive power is placed between the consumer and infectious disease by the substitution of aerated for ordinary drinking water, at any rate in times of epidemics, is to a certain extent justified by investigation.

Although storage, even for such considerable periods of time as over two years, cannot — at any rate in some cases — secure the entire elimination of ordinary water microbes, yet storage of considerably shorter duration is of undoubted service in the destruction of disease germs.

THE DANGER OF SEWER-GAS, AND THE EXCLUSION OF THE SAME FROM DWELLINGS.⁵

The authorities who had been prominent in the past in laying down the doctrine of the promulgation

of diseases through the agency of sewer-gas were discussed, and the writings of Parkes, Meredith, Notter, and others were cited. It was chiefly in England that the injurious action of sewer-gases escaping into houses was insisted upon, and typhoid fever was one of the principal diseases attributed to these causes. The reports of Simon on the Sherborne epidemic in 1872, and of Buchanan on the outbreak of typhoid fever at Caius College in 1873, are quoted as representative of the opinion of English experts. In contradistinction to these views, the majority of writers on hygiene in Germany maintain that sewer-gases are incapable of disseminating typhoid fever or other infectious diseases; and, in support of these conclusions, allusion is made to the investigations of Flügge, Gärtner, Prausnitz, Rubner, and Soyka.

As early as 1881 the last-named authority demonstrated by statistics at the Vienna meeting of the society, that cities provided with sewers were not in any way more liable to the attacks of diseases of this type than those wholly undrained; indeed, he proved the converse of this theory, and showed that in a series of towns which had recently been sewered on the modern system the mortality from typhoid fever had diminished, and that, in those parts of the towns where the sewerage was defective, the cases of typhoid fever were more frequent and more severe than in those quarters which were well drained. Many other authorities were cited, and figures are given to show the condition of drained and undrained towns, among which the facts relating to Dantzic and Munich before and after the introduction of drainage are recorded, also the investigations of Baron into thirty-seven undrained towns and forty-six towns provided with a system of sewers. Everything pointed to the opinion that the provision of proper drainage is the best method of reducing the death-rate from typhoid fever;⁶ whereas, if the sewer-gas theory were correct, the construction of a modern sewerage system ought to entail increased mortality from this disease.

Passing on to the discoveries of Pasteur and Koch and their numerous pupils, the author shows that a correct knowledge has now been gained of actual disease-germs, and of the best means of withstanding them. It may be pronounced with absolute certainty that any given disease can only occur when the known organism recognized as the active agent of the same has acquired vitality. In the absence of the typhoid-bacillus there can be no typhoid fever; and where there is no cholera-vibrio, there can be no cholera. The gases caused by putrefaction, however poisonous they may be, cannot produce diseases of the above kind. The author points out that certain of these pathogenic germs which may enter the sewers mixed with fecal matters and soiled water do not find in them very favorable conditions for their existence, and that for the most part these organisms lose their virulence in sewage water. In order that the sewer-gas theory may be realized, it must, however, be assumed that certain of these infectious germs are capable of floating in the air and of thus entering dwellings. Nägeli has, however, shown that this is not possible, and he has proved that these germs can neither ascend into the air nor be given off from moist surfaces, and in the air of sewers, moreover, bacteria have been ascertained to be invariably present in small numbers;

⁴ Public Health, London, February, 1897, p. 167.

⁵ Dr. M. Kirchner: Deutsche Vierteljahrsschrift für öff. Gesundheitspflege, 1896, xxviii, p. 152.

⁶ This statement needs qualification. It would hardly seem possible that the writer intended to exclude the influence of pure and unpolluted water-supplies as an important factor. — Editor.

indeed, frequently such air is absolutely free from these organisms. Uffmann has been at some pains to ascertain the species of bacilli found in sewer-gas, and a list of these is given. It is stated that it follows from these arguments that there is no proof of there being any connection between sewer-gas and the spread of epidemic diseases.

On the question of the extent to which, apart from their liability to spread diseases, sewer-gases may prove injurious to health, the author asserts that this depends mainly on the degree of concentration in which certain undoubtedly poisonous gases exist which are found in sewers and other places where putrefying matters are collected and stored. The thorough and effective ventilation of sewers and soil-pipes is the best mode of combating this evil.

A distinction is drawn between sewer-air and sewer-gas, and it is pointed out that the latter can only form in sewers which contain dead-ends and in other places where effective ventilation is wanting. In well-constructed sewers, the contents pass away freely and rapidly without undergoing putrefaction, and the air in such sewers is in no way unhealthy. The house-drains and soil-pipes are much more likely to engender evil-smelling and injurious gases than are the sewers.

A further experimental paper on this subject appears in the "Transactions of the American Society of Physicians and Surgeons," 1894, Vol. III, p. 28, under the title of "Chemical, Physical and Bacteriological Studies, upon Air over Decomposing Surfaces, with Special Reference to their Application to the Air of Sewers," by Prof. A. C. Abbott, of the University of Pennsylvania. His conclusions appear to coincide with those of Dr. Kirchner.

SHELL-FISH AND DISEASE.⁷

It seems to me that a few points should be clearly stated, and some conclusions drawn, as to the future regulation of our shell-fish trade. In the first place, out of the various forms of human poisoning which can be caused by food, shell-fish, under unhealthy conditions, may give rise to two which are very distinct from one another. They are (1) bacterial infection, due to the presence of actual living disease germs, derived presumably from sewage; (2) intoxication with organic poisons developed in the body of the oyster or mussel.

"Professor Boyce and I have been working at this subject — oysters and disease — for the last two years, and a year ago we recommended (in my report for 1895 on the Lancashire Sea Fisheries Laboratory) two sanitary measures, namely, first the inspection of all grounds upon which shell-fish are grown or bedded, so as to ensure their practical freedom from sewage; and, secondly, the use, when necessary, of what the French call *degorgoirs* — tanks of clean water, in which the oysters should be placed for a short time before they are sent to the consumer. I am inclined now to suggest that a combination of these two methods would be a practical and satisfactory solution of the present difficulty. The *degorgoirs* may be regarded as a precautionary measure of the nature of quarantine, to which oysters from foreign or unknown beds, or such as are suspected from any reason, should be subjected.

"Our experiments at University College have shown,

as Professor Boyce announced to the Physiological Section at the recent British Association meeting, that it is easy to get rid of bacterial infection by placing the shell-fish in a stream of running water. When oysters were infected with typhoid, and were then placed in a series of vessels through which a stream of sea-water was kept running, it was found that there was a great diminution or total disappearance of the typhoid bacillus in from one to seven days. The water need not be sea-water, as oysters frequently live in estuaries which are brackish, or at times almost wholly fresh; and I may add, for the comfort of troubled housekeepers, that a clean vessel in the pantry sink under the running tap is a very fair substitute for our more elaborate experimental apparatus, and that even one day makes a great deal of difference in the washing out of the germs. I need scarcely say that the oysters must be alive. It is no use subjecting oysters that have been opened to this prolonged soaking. The essence of the *degorgement* treatment is that the living animal purifies itself.

"Authoritative inspection and licensing of the shell-fish grounds would, no doubt, result in many beds being at once certified as quite healthy, and oysters from these might then be sold without restrictions, and consumed with peace of mind; a few localities, which are discussed in the Local Government Board Report, would be at once condemned as unsuitable to have any connection whatever with human food; while there would remain a number of spots in estuaries or near large towns where the conditions are not absolutely bad, and are not wholly good, and oysters from such places should be subjected to the *degorgement* treatment before being sold. One other simple piece of advice: The oyster ought to be obtained as fresh as possible from the sea, or from moving water. It is not good for any animal — the oyster is like its consumer in this as in many other respects — to be shut up in a barrel or a sack for days or weeks; and if you put the oyster under unhealthy conditions, you will probably eat unhealthy oysters.

"A careful consideration, then, of our own experiments, and of the evidence given in the recent Local Government Board Report and derived from other sources, leads us to the conclusion that what is indicated at the present time is that (1) some fisheries or sanitary authority should offer to inspect the grounds, and certify as to their condition; (2) the oyster growers and merchants should unite in an effort to remove all grounds for suspicion by allowing biological as well as economical considerations to weigh with them in their choice of localities for 'laying'; and (3) the public should not give way to unnecessary alarm. We cannot escape disease germs, and we probably, all of us, encounter them frequently without suffering any consequences. Shell-fish only share with milk, bread, cold meat, the water we drink, and the air we breathe, the responsibility of occasionally being liable to convey disease to the human body, and that is no sufficient reason for avoiding what is otherwise healthy food. Common-sense on the part of the public, reform where necessary by the oyster trade, and regulation by some impartial authority, ought to enable us to feed on healthy oysters with an easy mind."

REGISTRATION OF APOTHECARIES.

The Imperial German Board of Health has issued a report upon the Registration of Apothecaries in Ger-

⁷ Prof. W. A. Herdman: Sanitary Record, London, January 29, 1897; Liverpool Post.

many,⁸ which shows that the relative number is much less than it is in this country.

The number (comparing those of 1887 with those of 1895) of apothecary shops in large, medium and small municipalities had experienced the following changes:

There was one drug-store to the following number of inhabitants:

	1895.	1887.
In large municipalities	11,149	11,322
In medium-sized municipalities	6,855	6,306
In small-sized municipalities	10,037	9,757

The report is accompanied with very full statistical tables, presenting the distributions of drug-shops, as well as of druggists and their assistants, together with two excellent maps showing the same distribution as estimated upon the census of July 1, 1895.

Reports of Societies.

MASSACHUSETTS MEDICO-LEGAL SOCIETY.

JULIAN A. MEAD, M.D., SECRETARY.

THE Society met at No. 19 Boylston Place, February 3, 1897, the President, Dr. S. W. ABBOTT, in the chair.

HON. H. M. KNOWLTON, Attorney-General of Massachusetts, addressed the Society on

THE DUTIES OF A MEDICAL EXAMINER.¹

DR. E. P. HURD, of Newburyport: I would like to have had the speaker more explicit on the question of suicides. If I understood the gentleman, when a medical examiner is called to a case where he finds a body, if it is a case of suicide, he has nothing to do with the case at all. Perhaps I misunderstood him. In a discussion before another association, the gentleman who read the paper at that time took the ground that this class of cases did belong to the medical examiners to determine the fact of suicide. The other case is the case of drowning, where the case is palpable: as where a child goes in swimming, or rowing in a boat, and there are half-a-dozen persons who saw the drowning accident. The body is brought ashore, and the medical examiner sent for. I would like to know, because I live on the border of a river near the shore, where we have more cases of death by drowning than through so-called "violent" deaths; I would like to know specifically—supposing I am summoned to go three miles to a drowning case, and there are plenty of witnesses who saw the party go in bathing, and perhaps brought the body ashore—what my duty is. Is it to obey the summons and get a report on the case, or satisfy myself that there are no doubts that it is a case of accidental drowning? Is it my duty to report it or leave it unreported?

MR. KNOWLTON: Of course, the death by drowning illustrates the general proposition. A death by drowning is an "unnatural" death, and so far comes within the province of the medical examiner. Then I adhere to what I said, that if the fact of suicide is clearly established, there is no crime to punish and no

occasion for further proceedings. I should say without doubt that whenever a case of drowning is reported to you, it is your duty to view the body, because nobody can tell so well as the medical examiner. He is the instrument of the Commonwealth to ascertain—the Commonwealth has appointed him to ascertain—whether it is death by drowning, or not. When he has ascertained by personal inquiry and by view, to his own satisfaction, he has no occasion to go further unless there are circumstances requiring him to go further.

In regard to the other question: I can only say as I said before that it is the medical examiner's business to go to the length of ascertaining whether "the unlawful act of another" contributed to the death. At any time when he becomes satisfied that the act of another did not contribute to the death, then his duty is discharged; because suicide is not punishable in this Commonwealth as a crime, the ingenious argument two years ago, to which I listened, to the contrary notwithstanding. The confusion in this rose out of the fact that the case of suicide presents a case where there is an obviously human force—human physical force—used, and the ascertainment of the fact becomes therefore more difficult whether it is the force of the man himself or some one else. After the view has settled it that it is the force of the man himself, and a suicide, then there is no crime. Of course, that addresses itself to the judgment of the medical examiner. He is to bear in mind that when he has traced out the end of the man—whether it is a man found dead in bed with a pistol-shot, and the pistol in his hand; or a case of asphyxiation, with the gas turned on; or any case of suicide—if the results of his view do not point clearly to suicide, of course, it is possible to go further.

DR. SAWYER: I should like to ask the attorney-general if his remarks are applicable to cases of burning. I did not understand him to answer directly another part of the question asked in the previous question, whether the medical examiner would in his opinion be justified in making a charge for such an examination?

MR. KNOWLTON: I did mean to say that every "view" should be charged; that the Commonwealth don't expect anybody to work for nothing, and the amount is earned by the investigation. The body has been killed by the hand of man or by the elements, and his charge is for ascertaining which one of these. "Burning" is an unnatural death; it may be death by violence or by accident, and he came to the "view" for the purpose of determining that question.

The Society was addressed by HON. SHERMAN HOAR, United States Attorney for the District of Massachusetts, on

THE MEDICAL EXAMINER AS A WITNESS.²

DR. BRONSON: This gentleman says that he don't think that the medical examiner should take issue against the State. What does he mean by that?

MR. HOAR: I mean exactly this, that I think the medical examiner is a part of the machinery of the State; and while he should keep his mind entirely open and tell the exact truth, while he should give his opinion exactly, he should never be found as an "expert" on the other side where the State is involved. I think it damages his professional standing as a witness whenever he comes forward later as a

¹ See page 321 of the Journal.

⁸ Die Verhretung der pharmazeutischen Anstalten und des pharmazeutischen Personals im Deutschen Reiche nach den amtlichen Erhebungen von Juli 1, 1895. Berichterstatter Sanitätsrath, Dr. Würzburg, Berlin.

² See page 330 of the Journal.

witness for the Commonwealth. I think the willingness often shown in cases to testify against the Commonwealth as an "expert" against those chosen by the Commonwealth to be medical examiners, and in opposition to the view taken by them, has a tendency to degrade in the public mind the position of the medical examiner.

DR. BRONSON: I agree with my friend, the district attorney, on this subject; but there is one question involved here on which I desire to ask his advice as an ex-medical examiner. He, of course, has recently conducted a cause in the interest of the United States against a man who was alleged to have committed murder upon the high seas. Two experts were brought into that case (medical experts). One, examined by the defence, was present during that trial and was examined as to the mental status, so far as he could give it, of a certain witness in the case; and upon being brought upon the stand, he alleged that in his opinion that man was insane. The antecedent history emphasized that opinion, as I understand it. And he went into the record as a believer in the unsoundness of that man's mind. When the question was submitted to analysis, men who believed in the standing and character of that expert believed, I think, as a rule, that that witness was unsound mentally. Later, the district attorney called an expert who has charge of one of our insane asylums, and he took an adverse position. He declared his belief that that man was not insane, not unsound mentally, and that he had not been unsound at Rotterdam years before.

Now, in the case of that kind of questioning, I desire to ask the district attorney as to how he is going to harmonize views — those two statements — by any process other than that of reason? If Dr. X had been sent there by the United States, would he, in the opinion of the district attorney, have entertained views adverse to those he expressed when examined there by the defence? If so, this, of course, is a warping of that man's judgment based upon the method by which he was brought there as a medical expert.

MR. HOAR: I must decline to criticise any of the witnesses that have been in the case I have personally conducted. But I will say to my friend that I should like nothing better than to have it in the power of any court to appoint medical experts to give a definite decision, unbiased by the fact that they were called as witnesses on either side. I believe that that is essential, for the reason that the doctor states here. Men unconsciously take sides. They can't help it; I do it myself. Men do it honestly. If it were best for the court (it could not be done, in my judgment, without giving either side the entire right to call medical witnesses) in a case where opinion is given on either side, to examine men of character and unbiased, selected by the court and not by the counsel, to get their judgment, it would materially help twelve men, laymen, to decide the question at issue. And I should like to see that done.

I cannot discuss the particular matter stated here. And there is nothing, as long as our jury system exists — and I am a thorough believer in it, because I believe in my experience with judges and lawyers and doctors that the ordinary Yankee gunption of twelve men is apt to be right as much as that of

twelve educated men — but to rely upon the natural sagacity to detect flaws in even medical testimony, and to "size up" men even if they are doctors.

DR. SAWYER: There is quite a tendency, I believe, to call upon medical examiners as experts in the courts in cases where medical expert evidence or opinion is necessary. I would like to ask the attorney-general if he would consider it at all detrimental for the medical examiner to appear in such a case as that, where he does not appear contrary to the interests of the Commonwealth?

MR. KNOWLTON: In civil cases I see no objection at all.

DR. SAWYER: Pardon me. But there was one matter about which the attorney-general made the statement that a medical examiner should hesitate some little time before coming into the district of another medical examiner, but that where cases demanded immediate action he should respond at once. Now I have been a little embarrassed. I have been summoned two or three times into surrounding districts when the medical examiner was not at home at that time — summoned by the legal officers or selectmen; in one instance, by the chief of police of the city of Fitchburg. Just how far ought a medical examiner to intrude upon the jurisdiction of another medical examiner?

MR. KNOWLTON: The law distinctly provides that, although medical examiners are appointed by districts, that provision should not be construed as preventing them from acting in any other part of the county. I think it does not extend to another county. So there is nothing in the law that will prevent a man who has one district in a county going into another district of the county. Two things are to be considered in answering such a question. The first is, that it often happens that the whole consequences may depend upon immediate action. For example (I meant to have spoken of this in my address), it happens in my experience to an unusual degree that the question of how long the body had been dead is liable to be of vital importance; and that, of course, can only be determined with any accuracy by an immediate "view." I think the experience in several recent cases has impressed upon the several medical examiners the great importance of getting the temperature of the body more accurately than can be ascertained by the somewhat fallacious nerves of the hands — some accurate measurement of the temperature. Secondly, his own immediate success will lead him to see where for any reason his services are more in demand than those of the medical examiner of the district; and if the alleged temporary absence of any other examiner is a pretence to get the more favorite examiner he will find himself judge. There is no law but the unwritten law of courtesy; the unwritten right of each man to have whatever belongs to his district is only to be overridden when for any reason whatever there is reason for special haste. This is not a good answer, but it is all I can give.

DR. MEAD: Is there any regulation as to when a medical examiner should make an autopsy?

MR. KNOWLTON: Fortunately, the law is pretty plain about that. It imposes it on the discretion of the medical examiner, "if after having viewed the body and made the special inquiry, he deems a further examination necessary." If he shall proceed to make an autopsy upon the authority of the district attorney,

it then comes to the final discretion of the judgment of the man who is commissioned by the governor to use his discretion. I say, answering the proposed question by examples more than by principles, Where he becomes reasonably satisfied, without an autopsy, that there is no violence, he should not have an autopsy. Where he is left in doubt, and he thinks an autopsy will help him, he should have it. Where the cause of death is apparently "the unlawful act of another," then he should have an autopsy, not for the purpose of satisfying himself as to whether there was crime or not, but for the importance of the evidence that may be developed by the autopsy.

DR. MEAD: There is a subsequent law which says that the fee shall be paid only when the district attorney shall certify that the autopsy was necessary. It takes it out of the hands of the medical examiner.

MR. KNOWLTON: I remember that law; and it was passed undoubtedly in consequence of the fact that one or two medical examiners (one that I knew something about—not living) I am sorry to say were in the habit of looking at pecuniary results rather than the cause of justice.

I do not know how far the experience of medical examiners can correct the statement; but in my experience, with perhaps one single exception, I have considered the judgment of the medical examiners to be better than my own. And I have never refused the certificate when the examiner has thought he ought to make the examination. The most that can be said is, that if the district attorney does not agree, the examiner has no fees. But there again I would suggest that when the question comes up as to whether a view is necessary, or an autopsy, he should proceed regardless of whether he is making the county an expense or not, and regardless of the fact whether he is going to get anything out of it.

DR. DRAPER: I move the cordial thanks of the Society be given to Mr. Knowlton and Mr. Hoar for their lucid, useful and helpful interpretation of various doubtful points which have troubled us.

The motion was adopted with applause.

The next subject brought before the Society was a paper by DR. W. F. WHITNEY, entitled

THE IDENTIFICATION OF SEMINAL STAINS.*

In reference to the subject of

MEDICAL EXPERT TESTIMONY

it was voted that the Executive Committee of the Society be instructed to co-operate with committees appointed by other bodies, legal and medical, in attempts to secure legislation to reform the present methods of employing medical experts in the courts of this Commonwealth.

A COSMETIC LAPAROTOMY. — Küstner, of Breslau,¹ has proposed a transverse skin incision in the fold of skin which often occurs at about the upper limit of the pubic hair in women. This superficial incision being well retracted, the ordinary median incision is made in the *luna alba*. The linear skin cicatrix is rendered almost invisible by the pubic hair and the natural crease in the skin.

CEREBRO-SPINAL MENINGITIS A DISEASE DANGEROUS TO THE PUBLIC HEALTH.

ALONG with the growth and increasing density of population the tendency of progress in preventive medicine is in the direction of giving greater and more definite powers to boards of health, for the investigation and the prevention of the spread of infectious diseases. Many years ago (1827) laws were enacted in Massachusetts making it the duty of householders, and of physicians to report to the selectmen or boards of health of towns, the existence of small-pox, or of *any other disease dangerous to the public health*; and in 1883, the boards of health were required to transmit the same information to the State Board of Health, so far as small-pox was concerned. In 1893 the law was made more explicit, and local boards were required to transmit immediate information to the State Board as to the existence of *all diseases dangerous to the public health*. This term, "*other diseases dangerous*," etc., was not defined by statute, but left in an indefinite manner.

A somewhat similar act was recently passed in England. A dozen or more diseases were specified in the English act as notifiable, but power was given to sanitary authorities to order that the act shall apply to *any other diseases* besides those which are specified.

The following statutes are now in force in Massachusetts:

[PUBLIC STATUTES, CHAP. 80, SECT. 78, ACTS OF 1884, CHAP. 98, AND ACTS OF 1891, CHAP. 188.]

(1) When a householder knows that a person within his family is sick of small-pox, diphtheria, scarlet fever or any other disease dangerous to the public health, he shall immediately give notice thereof to the selectmen or board of health of the town in which he dwells, and upon the death, recovery or removal of such person, the rooms occupied and the articles used by him shall be disinfected by such householder in a manner approved by the board of health. Any person neglecting or refusing to comply with either of the above provisions shall forfeit a sum not exceeding one hundred dollars.

(2) When a physician knows that a person whom he is called to visit is infected with small-pox, diphtheria, scarlet fever or any other disease dangerous to public health, he shall imme-

diately give notice thereof in writing, over his own signature, to the selectmen or board of health of the town; and if he refuses or neglects to give such notice he shall forfeit for each offence not less than fifty nor more than two hundred dollars.

[CHAPTER 302 OF THE ACTS OF 1893.]

(1) When the board of health of any city or town has had notice of the occurrence of a case of small-pox or any other disease dangerous to the public health in such city or town, such board of health shall, within twenty-four hours after the receipt of such notice, notify the State board of health of the same.

In order to facilitate the operation of these acts, the State Board has prepared and furnishes to local boards an ample supply of blank postal-cards, by means of which the local authorities can supply the information required in the act. A circular was issued in 1893, in which the State Board expressed its opinion that the following diseases should be regarded as dangerous to the public health, within the meaning of the act: small-pox, scarlet-fever, measles, typhoid fever, diphtheria, membranous croup, cholera, yellow fever, typhus fever, *cerebro-spinal meningitis*, hydrophobia, malignant pustule, leprosy and trichinosis.

The first six of these diseases, except small-pox, are of much more frequent occurrence than the remainder, consequently, these six are placed at the top of the postals, and a blank space is left for recording the number of cases of each disease. At the bottom of each card, however, attention is called to certain other diseases, *cerebro-spinal meningitis* being named among them.

It appears that during the past month this disease has been prevalent to an unusual degree; and yet scarcely any notice has been taken of the fact in the usual notices forwarded to the State Board of Health by local boards. This is undoubtedly due to the neglect of physicians to notify the local boards of its existence. It is quite desirable that all such diseases as may occur at intervals in epidemic form may be made the subject of notification, in order that the State Board may receive the fullest information upon the subject.

It is only a few years since a serious epidemic of trichinosis occurred in one of the small towns west of the Connecticut river, in which about fifty persons were taken ill and five died. The State Board received no notice whatever of its occurrence from the local authorities, and only learned of the same through accidental and non-official sources.

Cerebro-spinal meningitis is much more prevalent in the United States than in Europe. The number of deaths from this cause, as stated by Dr. Billings in the census of 1880, was 2,898 in the United States in that year, and allowing for deficiencies the actual number was probably about 4,000. Of the number recorded, 35 per cent. were under two years of age, and over 80 per cent. were under five years of age.

In Massachusetts the total number of deaths from the same cause in the five years 1891-1895 was 574; of which number 231, or 40 per cent., were under two years of age.

In England at no time in the past twenty years did the number of registered deaths from this cause exceed

58 in any single year in a population averaging 25 millions.

Within the past few weeks *cerebro-spinal meningitis* has occupied the attention of the profession in Boston and its neighborhood, from the occurrence of cases both in hospital and in private practice; and a rapidly fatal termination of the attack in two prominent citizens has emphasized this attention.

In several instances lumbar puncture has yielded a *diplococcus* differing from the *pneumococcus*.

The suddenness of the onset, the rapidity of the course, the resistance to any form of treatment in the majority of cases, together with the large percentage of mortality, and the impossibility in most cases of tracing the source of infection, render this disease one dreadful alike to the patient and to the physician.

"PLASTER CASTS" AND "WALKING CASTS."

"AND was your leg broken when you fell?" "No docther, it wasn't broken, but the docther at the hospital said it was badly fractured, and he kept it in a plaster cast for two months before he let me bear me weight on it." Such is the class of people by whom the surgeon hears the term "plaster cast" employed most frequently in the sense of plaster bandage or dressing, and the "caste" of such people might on the average be said to be as low as their treatment of the English language. The name seems to have come to be used in this sense by the frequency with which casts, or reproductions of the form of objects by liquid material run into a mould and allowed to solidify, are made of plaster. Anything made of plaster, even a stiff bandage, which might if removed be used as a mould to make a cast in, becomes a "cast."

Of late, however, we have observed with regret, combined with pity, perhaps undeserved, that the use of the term cast as applied to bandages stiffened with plaster-of-Paris is not confined to the class of people who so frequently inform out-patient surgeons that the leg was not broken, only fractured, but that medical students are talking in groups about the relative merits of splints and plaster "casts" in the treatment of fractures, and even instructors in our large medical schools are talking about the treatment of fractures by plaster casts. The ambulatory treatment of fractures of the lower extremity has walked into prominence leading by the hand the "walking cast," which let it be understood, is not a cast endowed with legs and powers of locomotion, as its name would imply, but a bandage stiffened by plaster-of-Paris and so applied that a patient may walk on it without injury to the fractured member which it eueases. Contributors to some of our well-known medical journals, whose editors would be shocked at any misuse of the English language in those columns, are allowed to write about "walking casts," and "plaster casts," giving the term "cast" a meaning contrary to good sense and good English. Let these unwarranted expressions be cast out of medical terminology!

MEDICAL INSPECTION OF SCHOOLS IN NEW YORK.

THE results accomplished in the first four days of its work by the recently established Division of the Medical School Inspection of the Health Department show the great need that existed for such inspection, and sufficiently demonstrates the fact that the appropriation made by the city for this object is money well expended. During that time more than four hundred children have been found suffering from contagious diseases and excluded from the schools.

As was to have been expected, the great proportion of cases discovered were of diseases of the eyes and skin, but a considerable number of instances of acute infectious disorders have also been detected. Among these were ten cases of supposed diphtheria, two of measles, one of scarlet fever, and six of mumps.

In the cases of supposed diphtheria the children were all promptly isolated, to await the result of cultures, and at the time the report was made six of the ten children had been shown to be suffering from attacks of true diphtheria. In none of these cases, it is stated, had either the parents or teachers suspected the presence of that disease.

The plan of school inspection now inaugurated includes a course of lectures to be given to teachers for the purpose of aiding them in a general way to themselves detect the various contagious diseases liable to be met with among school children. This medical inspection of schools, which was started here in Boston, is commending itself so strongly by experience that it will probably become general wherever considerable numbers of children are gathered together in schools.

MEDICAL NOTES.

DEATH OF AN OLD PRACTITIONER. — M. Boisson, the oldest medical practitioner in France, died last week at Havre, at the age of one hundred and two. At the time of his death he was still in active practice.

PROFESSOR HANKIN ATTACKED BY PLAGUE. — Professor Hankin, who has done so much work in connection with plague in India, was recently attacked by the disease at Agra. He was inoculated with Haffkine's serum, and his recovery is regarded as certain.

CHLOROFORM FATALITIES. — The increasing frequency of deaths under the influence of chloroform is attracting attention. The mortality for the months of January and February of this year amounted to twelve deaths as against seven for the corresponding weeks of last year. — *Medical Press and Circular*.

CREOLIN AFTER ABDOMINAL OPERATIONS. — J. Malseed Bell¹ has found that by the vaporization of ten or fifteen drops of creolin over a spirit flame, and the inhalation of the vapor, the irritative cough which sometimes results from etherization and is so troublesome in abdominal cases from the strain which it produces on the wound, may be allayed until the

convalescence is so far established that other means may be employed. This is certainly a simple, and apparently rational method for treating a troublesome condition, and as such deserves trial.

THE MECCA PILGRIMAGE SUSPENDED. — The Governor-General of India has ordered the suspension of the pilgrimage to the Hedjaz for the current season, the government of India having come to the conclusion that in consequence of the strong opinions of all the European governments, including Turkey, regarding the danger of the plague being communicated to Europe, it is impossible to meet their demands by any measure short of suspension of the pilgrimage for the time being.

CRUELTY TO HORSES IN ANTWERP. — It is reported that the English and American residents of Antwerp are endeavoring to have an abattoir for horses built near the docks, so that they may no longer be obliged to witness the mournful procession of decrepit and worn-out horses on their way to the present abattoir. The *Lancet* protests against these poor creatures being obliged to make a long and exhausting journey in addition to the sufferings of their sea voyage from England to the land of the hippophagi. "If any one is permitted to sell horseflesh for foreigners to eat," says our contemporary, "it should be killed on this side."

THE SCIENTIFIC ASPECTS OF THE RECENT GLOVE FIGHT. — That distinguished exponent of the manly art of self-defence, Mr. Robert Fitzsimmons, would hardly feel complimented were he to read the remarks of the *Medical Press and Circular* upon the character of the blow by which he recently won the heavy-weight championship. "The deciding buffet," says our contemporary, "was evidently one administered over the celiac plexus, called a blow on the heart, really on the stomach. The referee described it as 'an underarm punch,' just below, and slightly to the right of the heart, which is, being interpreted, the pit of the stomach. By the laws of the ring, the blow is a fair one. By the rules of common humanity, however, it is a cowardly outrage little short of a deliberate attempt at assassination. The fatal nature of a severe blow to the network of visceral nerves, known as the celiac plexus, makes such 'punches' as those which finished Corbett among the most deadly that can be inflicted with the fist. By the way, what have the anti-vivisectionists to say to this brutality inflicted by man upon man?"

THE HEALTH OF THE FRENCH ARMY. — According to a report by the French Minister of War, recently published in the *Journal Officiel*, new methods of sanitation have resulted in a steady improvement in the hygiene of the French troops. Owing to the use of spring water or the Pasteur-Chamberland filter, typhoid fever has disappeared from some garrisons which it formerly decimated. It is proposed to introduce steam sterilizers into the barracks, and furnish facilities for boiling all the water used by the garrisons. The army is less subject to small-pox, and re-vaccina-

¹ Medical Record, April 3, 1897.

tion has preserved the troops in Algeria, Madagascar and Tonquin, where it is prevalent among the native populations.

HOSPITAL TREATMENT FOR PHYSICIANS.—The Trustees of the Philadelphia Polyclinic have recently adopted the following resolution:

Resolved, That the Trustees of the Philadelphia Polyclinic and College for Graduates in Medicine, wishing to show their appreciation of the public services of physicians upon whose skill and faithfulness all successful hospital work depends, order that one of the private rooms in the Polyclinic Hospital be called the Room of the Mutual Aid Association of the Philadelphia County Medical Society, and direct the Superintendent to admit to said room without charge any member of the Mutual Aid Association of the Philadelphia County Medical Society who may be sick and require medical treatment; provided, that the officers of said Association first certify that the applicant's circumstances require such concession in regard to hospital charges; and that the rules of the hospital in other respects in regard to the admission and duration of stay of patients be observed, and that nothing in these resolutions shall be construed to prevent the use of the said room for other patients at regular rates when it is not occupied by a member of the Association named.

THE POSSIBILITIES OF EUPHEMY.—An English nurse recently brought a suit for breach of promise of marriage against a surgeon, and got judgment in the sum of £300. The surgeon claimed that she had misrepresented her social position, stating that her father was well-to-do, and connected with the Church of England, that her brother was an engineer, and that she had gone into nursing merely to avoid a life of inglorious ease. At the trial it was brought out that her father was "connected with the Church," in the capacity of berger, that her brother was an artisan, and that she had taken up nursing as a means of livelihood. "The surgeon did well," says an English contemporary, "to escape a misalliance at a cost of a paltry £300. The tears that Cupid must have shed, at the edifying spectacle, of the motives governing the participants in this 'love affair' as brought out in court, must they count for nothing?"

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, March 31, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 75, scarlet fever 58, measles 150, typhoid fever 5. For the week ending April 7, the following cases were reported: diphtheria 91, scarlet fever 66, measles 113, typhoid fever 6.

ANNUAL REPORT OF THE BOSTON LYING-IN HOSPITAL.—From the annual report of the Boston Lying-in Hospital it appears that 678 patients were treated in its wards during 1896, and 680 children born. There were 11 deaths during confinement.

The Out-patient Department of the hospital treated 1,564 cases at their own homes, with no deaths.

Since 1873, when the McLean Street Hospital was opened, 8,428 patients have been treated in the wards; and since 1881, when the Out-patient Department was established, 9,463 out-patients have been attended

under the supervision of the hospital staff. Of the total number of patients treated since 1873 in the hospital, 145 have died; but of the 5,767 cases admitted since the introduction of the antiseptic methods of treatment, there have been only 53 deaths. Of the patients who have died, many have been brought to the hospital when almost beyond hope of recovery, in order to give them any possible chance which might be afforded by the care and treatment provided at the hospital.

Of the patients treated in 1896, 439 were married women, and 239 unmarried. The unmarried women received were not women of bad character, but those whose admission was urged on the ground of a needed service under unfortunate circumstances, or for serving the cause of public morality.

Since the nurses' training-school was established in 1888, 200 nurses have been graduated from the institution, and 126 house-officers have completed their terms of service and received the corporation's diploma.

Of the eleven patients who died in the hospital during 1896, four were brought there when seriously sick, and died soon after entrance. Of the three fatal cases of septicemia two had been confined outside, and were brought to the hospital in the hope that their lives might possibly be saved.

During the year three Cæsarean sections were performed at the hospital. All three mothers and two children were discharged well. The third, the ill-developed child of a cretin dwarf, died soon after the operation.

The hospital is dependent to the amount of \$10,000 annually upon donations in order to supplement its income from invested funds so as to avoid encroachment upon its capital. Money donations from friends of the hospital and grateful out-patients have brought it through 1896 with a small balance to its credit. It is hoped that the hospital may be no less fortunate in this than in previous years.

NEW YORK.

FIRE AT THE MANHATTAN STATE HOSPITAL.—A very serious fire occurred on the evening of March 30th in the Manhattan State Hospital on Ward's Island, which had 2,075 inmates at the time; but, owing to the admirable management of those in charge of the institution, a panic was averted and there was not a single casualty among the patients. The damage by the fire is estimated at nearly \$100,000, and plans for rebuilding have already been prepared. While the building is going on about five hundred of the patients will be cared for in other institutions, among them the Long Island State Hospital and the hospital at Central Islip.

OPPRESSIVE REQUIREMENTS OF THE GREATER NEW YORK CHARTER.—On April 2d Drs. A. Jacobi and T. E. Satterthwaite, representing the Academy of Medicine, waited upon Mayor Strong to protest against certain provisions of the charter of the Greater New York, one of which requires physicians

to report to the Board of Health all cases of pestilential disease occurring in their practice within three hours after a diagnosis has been made, and also to report any violation of this rule on the part of other practitioners that may come to their knowledge. It will doubtless be remembered that each of the mayors of the three cities of New York, Brooklyn and Long Island City, as well as the Governor of the State, has the right of veto in the matter of the charter, but the Legislature is empowered to adopt the charter in the face of such veto if the requisite majority can be obtained to vote for it.

IMPROVED TENEMENT-HOUSES.—A gratifying step in the work of the construction of improved tenement-houses has been taken by the City and Suburban Homes Company, which has just purchased from the managers of the Colored Home and Hospital (who will remove their institution to a suburban locality), the entire block on First Avenue, between 64th and 65th Streets, extending to the East River, on which it proposes to erect a group of model tenements. This company offers to those investing in it a return of five per cent. per annum on their money, and at the same time the satisfaction of providing comfortable and sanitary homes for the poor.

INCREASE IN THE MORTALITY OF THE STATE.—The monthly bulletin of the State Board of Health shows that during February there were 9,826 deaths in the State. This is an increase over the preceding month from a daily average of 310 to one of 350, and represents an annual death-rate per thousand of the estimated population of 19, against 17.25 in January. Among zymotic diseases there was a small increase in the deaths from cerebro-spinal meningitis, scarlet fever, measles and whooping-cough, while there was a decrease of 100 in the mortality from diphtheria. In the deaths from acute respiratory diseases there was a relative increase of 500 over the preceding month, and in those from pulmonary tuberculosis an increase of 125. About 300 deaths were attributed to influenza.

LOW MORTALITY IN NEW YORK CITY.—During the week ending April 3d there were reported in the city of New York 798 deaths, the smallest number for quite a number of weeks. The bright, dry weather which prevailed seems to have had an especially favorable effect on the mortality from pneumonia, the number of deaths from which decreased to 122, from 159 in the previous week. The week ending March 27th was notable from the fact that not a single death from typhoid fever was reported in it. During the week preceding there were two deaths from this disease, and in the week following, four deaths. During the past three weeks the number of deaths reported from influenza has been respectively 15, 17 and 7.

SMALL-POX IN NEW YORK CITY.—This week was also notable by reason of the circumstance that two deaths from small-pox were reported in it, the first that have occurred in the city for many months.

During the week ending April 3d there were no deaths from small-pox, but several cases of the disease were reported. Among them were two women at the New York Hospital, who had been admitted for other troubles, and a female helper at the Reception Hospital at the foot of East 16th Street.

DEATH OF DR. BRONSON.—Dr. John O. Bronson, a retired physician of eminence, died at his home at Rhinebeck, N. Y., on March 28th, at the age of seventy. He was educated at the Wesleyan University and the Sheffield Scientific School at Yale, and was a graduate of the old New York Medical College. For several years before the Civil War he was Professor of Anatomy at the latter school, and during the war he entered the medical service of the army. Later he served as chief medical officer of the Department of the Pacific, and afterwards occupied the same position in the Department of the South; the rank of Lieutenant-Colonel being given him for "faithful services."

Miscellany.

THE PROPOSED DUTY ON NATURAL MINERAL WATERS.

UNDER the existing tariff the duty on imported natural mineral waters is limited to one and one-quarter cents on the bottles in which these waters come, that is thirteen and one-half cents a dozen. Under the McKinley law the duty was eighteen cents a dozen. Previously and since 1872 we believe the existing rates obtained. Under the Dingley schedule, now before the United States Senate, we understand the duty on mineral waters in commercial quarts amounts to 66 $\frac{2}{3}$ per cent. *ad valorem*, and the supplementary duties on bottles larger than quarts carries the rates to 148 per cent. On the other hand, natural salts from mineral springs are transferred to the free list!

It is evident that such a duty is not for revenue, it is rather in the nature of a prohibitive tax.

It may be right and proper that foreign mineral waters should pay tribute if our government is to be supported by a tariff; but it is neither in the interest of revenue nor of the public and the medical profession that they should be prohibited. The duty proposed is more likely the result of an error in calculation than of intention, and we commend the petition which is in circulation for a revision of this rate by the Senate.

In 1890 a similar petition, very largely signed by physicians, was presented to Congress, and was favorably considered.

SPECIAL EXERCISES AT THE JUBILEE MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

DR. JOHN B. ROBERTS, Chairman of the Committee on Anniversary Exercises at the Jubilee Meeting of the American Medical Association, announces that the Committee of Arrangements has set aside an hour on the second day of the meeting for exercises to commemorate the founding of the Association in Philadelphia in

1847. The founders of the Association believed that it would raise the standard of medical education and combine the medical profession of the United States in one body. Dr. Davis, who is recognized by all as the moving spirit in the enterprise, will read a short paper, giving an account of the origin of the Association and how the objects for which it was founded have been attained. The Committee has taken steps to secure the attendance at the meeting of the Presidents of the State Medical Societies and the Presidents of the State Boards of Medical Examiners, as an illustration of the success attained through the instrumentality of the Association.

In addition to the address of Dr. Davis, there will be two or three other short addresses to add to the interest of the occasion. It is desired that the Presidents of all State Boards of Examiners and of all State Medical Societies meet Dr. Davis a few minutes before his address in order that they may escort him to the stage. In the event of the President of any one of these organizations not being able to attend the meeting, he is requested to send as an alternate, one of the ex-Presidents in order that every State Society and every Examining Board may be represented upon this notable occasion.

Of the original members of the Association there are still living, Dr. N. S. Davis, of Chicago, Dr. Alfred Stillé, of Philadelphia, Dr. John B. Johnson, of St. Louis, and Dr. David F. Atwater, of Springfield, Mass. The Committee hopes that these gentlemen will all be present to take part in the meeting.

THE TWELFTH INTERNATIONAL MEDICAL CONGRESS.

DRS. N. SENN, Casey A. Wood, Harold N. Moyer, Eugene S. Talbot, D. R. Brower, J. B. Murphy, D. A. K. Steele and B. T. Whitmore, believing that the comfort of those American physicians who, with their relatives and friends, intend visiting Moscow during the meeting, next August, of the Twelfth International Medical Congress, will be greatly enhanced, and the journey itself rendered more interesting and pleasant as well as more economical, by proceeding as one party instead of travelling singly or in small groups, have secured considerable reductions in the ordinary steamship, railway and hotel rates, and have succeeded in arranging three itineraries with the well-known tourists' agents, Messrs. Cook & Sons.

An educated conductor will accompany each section of the party, and the journey may be broken at almost any point, to meet emergencies. Those wishing to travel in this way should communicate with Messrs. Cook & Sons.

Obituary.

GEORGE B. TWITCHELL, M.D.

DR. GEORGE BROOKS TWITCHELL was born in Petersburg, Va., September 20, 1820. He was the son of Timothy and Susan (Watson) Twitchell. At ten years of age he was sent to Keene, N. H., to be educated under the supervision of his uncle, the famous Dr. Amos Twitchell, who was one of the most celebrated of American surgeons during the first half of the present century.

It may be remarked in passing, that probably comparatively few of this generation of medical men are aware of the fact that Amos Twitchell was the first man in this country to successfully tie the common carotid artery. This was done for secondary hemorrhage, the result of a gunshot wound, in October, 1807, nearly a year before Sir Astley Cooper's celebrated operation, and with only the assistance of an "old woman to wax his thread." During the while the doctor was controlling the hemorrhage by pressure with one hand, and dissecting out the vessel with the other. The patient recovered.

The subject of this sketch studied medicine with his uncle, attended lectures at the Harvard Medical School, and graduated from the University of Pennsylvania in April, 1843. He at once settled in Keene, where he soon took a leading position both as surgeon and physician and kept it during his long and active career. For a great many years he did most of the surgery in southwestern New Hampshire besides attending to a large consulting and family practice.

Possessed of a strong mind, clear and quick perception, firmness and decision of character, the courage of his convictions, the strictest honesty and integrity, a hater of shams and quacks—he inevitably became a leader of men, both in and out of his profession. He was not a blind follower of tradition, but did his own thinking. He was full of resources, as is shown by the fact, that upon one occasion, being called on to treat a case of post-partum hemorrhage, he did transfusion of blood with a Davidson's syringe, and saved his patient. He also did something in the way of reducing dislocation of the hip by manipulation before Bigelow's method was given to the profession. Having an excellent constitution, he was capable of an endless amount of work. Like the late Dr. Thorndike he was thoroughly imbued with an interest in his profession, took no vacations, kept abreast of the times, shrank from no operation or difficulties, and was a fitting example of the all-round, competent, progressive, reliable physician.

Dr. Twitchell went to the war in 1862 as surgeon of the 13th Regiment New Hampshire Volunteers, and was "soon promoted upon the field to brigade surgeon, and in March 1863 was commissioned by President Lincoln a surgeon of the United States Volunteers with the rank of major." While serving under General Grant at Vicksburg he contracted malaria, and was thus rendered unfit for active duty, and compelled to resign at the end of about a year's service.

For many years Dr. Twitchell was President of the Board of Trustees of the New Hampshire Insane Asylum, and a pavilion lately erected at that institution is named after him. He was also largely instrumental in the founding of the Elliot City Hospital in Keene, of which he has always been surgeon or consulting surgeon.

Dartmouth College conferred upon him the honorary degree of Master of Arts. He belonged to many organizations and societies, and was interested in everything pertaining to the well-being of the profession, and of the people. Although greatly interested in temperance matters, yet he was not a prohibitionist. He was actively identified with the introduction of aqueduct water, and the establishment of a sewerage system in his city, and was foremost in founding the public library, and supporting the schools and various charitable and public works of the town and State.

As showing the esteem in which Dr. Twitchell was held by his friends and neighbors mention may be made of the presentation to him on Thanksgiving Day, 1895, of a gold-lined (and gold-filled) silver loving-cup and salver of beautiful design, "the gift of nearly three hundred donors, including brother physicians, and citizens in every walk of life." The affair was so carefully managed that Dr. Twitchell knew nothing about it until he was quietly invited into his own drawing-room by a couple of his friends, and asked to open the box containing the gift.

In 1849 Dr. Twitchell married Susan Elizabeth, daughter of Gideon Thayer, the founder of Channey Hall School, by whom he had six children, four of whom survive him.

The two sons are members of the Massachusetts Medical Society.

On Monday, March 22, 1897, while attending to his patients Dr. Twitchell was seized with hiccoughs. They persisted more or less constantly for a week, except when he was under the influence of morphia, when coma, probably apoplectic, set in, and ended fatally in twenty-four hours.

His life was ideal in many respects, not the least of which was the fact, that he was enabled to labor in the profession he loved for fifty-four years, and to continue his work up to within forty-eight hours of the end.

GEORGE W. GAY, M.D.

Correspondence.

SYPHILIS IN RUSSIA.

BOSTON, March 31, 1897.

MR. EDITOR:—At the convention of Russian syphilologists, recently held at St. Petersburg, some interesting facts came to the surface, that may well engage the attention of both the specialist and the social reformer. It appears, that the scourge of syphilis is prevalent to a far wider extent than is even known to a great many of the physicians whose practice is entirely devoted to this special field. (Is not the same true of its extent here and elsewhere?) And while its rapid diffusion in the large manufacturing cities is generally by purely sexual contact, the inhabitants of the small cities and villages are mostly victims of syphilis insontium; this latter circumstance is entirely due to their almost primitive mode of living, total ignorance, and "pathetic" *naïveté*. As a result of these conditions, the number of those afflicted with the initial lesion, or first stage of the disorder, is far greater among children and the adults of the latter (small villages), than in the crowded centres of population. Places of yearly markets, religious pilgrimages and seaports, with their continually changing crowds of strangers, are the most prolific disseminators of the disease.

There seems to be little foundation for truth in the reputed assertion, that syphilis is less prevalent among the well-to-do, as compared with the poor and indigent; the reason of this lies in the fact, that alcoholism, which intensifies the sexual tendencies, and at the same time diminishes or entirely destroys the faculty for discriminating in the choice of gratification of these tendencies, is a curse that weighs heavy on all classes of Russian society.

Both legalized and secret prostitution are fertile causes in the spread of syphilis, especially among young adults of large cities, who appear to consider it a rather trifling and easily curable ailment; this ignorance naturally stands in the way of intelligent prophylaxis and tends to create almost criminal carelessness.

Another cause is found in the lack of free dispensaries for the treatment of the disease. (*O terra beata! lack [sic!] of dispensaries!*) In fact, the majority of cities—not to speak of villages—suffer from this lamentable condition, and the congress, among its other measures, recommends first of all the organization of a regular medical service, of a specialized character, to hold in check the ravages of the disease by establishing either special hospitals or separate departments in certain hospitals. It is particularly urged to supply medical aid to those in the stage of communicating the disease to others. It becomes necessary to make it obligatory upon working people of large manufacturing establishments, servants in hotels, bath-houses, bakeries, etc., to subject themselves to periodical medical examinations; and those found to be affected, are to be compelled, *pro bono publico*, to undergo a course of treatment.

The congress takes particular care to emphasize the importance of protecting the children from infection; the school must be guarded against becoming a hot bed of

the disease, and regular visits must be made for purposes of examination; any child that may communicate the disease must be rigidly kept away till its presence is no longer menacing. Regulations regarding vaccination must be subjected to a thorough revision, as many a case of "innocent" syphilis owes its existence to carelessness in performing this trifling operation.

I can hardly stop here to enumerate all the measures (a great many of them of a purely local character) proposed by the congress, in its determined battle against this terrible disease; but will conclude with its recommendation, that, to overcome the stupidity and ignorance of the village population, the medical profession come in closer contact with the latter, and by the aid of popular lectures, organization of reading-rooms and libraries, enlighten them on the true malignancy of syphilis. This, however, is the least practicable of all the propositions, as any step in the direction of lecturing to common people is looked upon with ill-disguised suspicion by the authorities, as liable to foster "revolutionary" ideas and insubordination; than which no more atrocious crime can possibly be committed by an Orthodox Russian subject; and so many obstacles are usually put in the way of the lecturer, that the warmest advocate will in the course of time become indifferent.

Very truly yours, A. ROVINSKY, M.D.

THE EXPERIMENTAL PRODUCTION OF FAT NECROSIS: FAT NECROSIS ABOUT THE PANCREAS OF THE HOG.

BY HERBERT U. WILLIAMS, M.D., BUFFALO, N. Y.,
From the Pathological Laboratory of the University of Buffalo.

THE relationship of fat necrosis to affections of the pancreas, and especially to pancreatitis, has been demonstrated by Fitz,¹ but the significance of this connection is not clear. The essential change in fat necrosis is a decomposition of the neutral fat molecule into its component fatty acid and glycerine. Frequently, if not always, the fatty acid unites with calcium to form a new compound, which is a soap. It is remarkable that the fat-splitting ferment of the pancreas accomplishes this very decomposition of neutral fats. Certain experiments reported within the last few years seem² likely to put us in the way of demonstrating the exact nature of the connection between fat necrosis and affections of the pancreas.

Hlava,² excited a hemorrhagic pancreatitis with fat necrosis in a cat by injecting the diphtheria bacillus into the pancreas after laparotomy.

Langerhans,³ suggested that the decomposition of neutral fats which occurs in this process might be accomplished by the fat-splitting ferment of the pancreas. He announced that he had succeeded in producing fat necrosis in a rabbit. This was the only positive result among twelve animals (rabbits and dogs) experimented upon. He made use of a suspension of rabbit's pancreas in distilled water, which was injected into the adipose tissues. His positive experiment is open to the objection that bacterial contamination was not excluded with certainty.

Hildebrand,⁴ and his student, Dettmar, placed a ligature about the gastro-splenic portion of the pancreas, to prevent the discharge of its secretion through the duct, in two cats, and in six others they performed the same operation and also ligated the veins leaving the organ. In all cases fat necrosis was found about the pancreas. They were also successful in producing it three times by introducing portions of the pancreas of one cat into the abdominal cavity of another. In one instance they obtained it after removing a piece from the organ and leaving the distal portion without ligature. Hildebrand, furthermore, injected pure trypsin into the abdominal cavity, and found that hemorrhages into the peritoneum resulted. He suggested that the hemorrhages, so frequent in pancreatic affections, might be due to the action of trypsin, while the fat-splitting ferment was responsible for fat necrosis.

Dr. Whitney, of the Harvard Medical School, allows me to state that he ligated the pancreas in a number of dogs and produced fat necrosis in one of them. No account of his work has been published.

Rosenbach, and his pupil Jung,⁵ with a similar object in view, introduced trypsin and at other times por-

tions of pancreas, into the abdominal cavities of rabbits. Out of four trials with pieces of pancreas they obtained fat necrosis once, using dog's pancreas.

As the work of Hildebrand has seemed to have been the most productive of results, the writer has attempted to verify his conclusions. The animals selected were two dogs, one rabbit, and seventeen cats. They were anesthetized with ether. The operations consisted in the placing of a ligature about the gastro-splenic portion of the pancreas near the duodenum, or the duodenal portion of the pancreas, or both. In most cases as many as possible of the veins leaving the pancreas were also tied. In the majority of cases a solution of continuity in the pancreas was effected. In one instance the gastro-splenic portion of the pancreas was cut through on the distal side of the ligature. An aseptic technique was followed, and the results were good with the exceptions noted below. The peritoneum and skin were closed separately with silk sutures. The wounds in the abdominal walls frequently furnished slight purulent discharges. Owing to the freedom allowed to the animals it was found impossible to secure primary union in every instance. Animals that died during the first twenty-four hours after operation are not included in this report.

The operations and their results in detail were as follows:

Dog. Weight 7 lbs., 1½ oz. A silk ligature was tied about the gastro-splenic portion of the pancreas. The animal, while apparently in perfect health, was killed at the end of one week; weight 8 lbs., 6½ oz. There was no peritonitis and no fat necrosis.

Dog. Large, fairly nourished. The gastro-splenic portion of the pancreas was ligated. The dog was killed after ten days, somewhat emaciated. There were adhesions and suppuration about the ligature, but no general peritonitis. There was no fat necrosis.

Rabbit. Moderately fat. The gastro-splenic portion of the pancreas was ligated. The animal remained in good condition, and was killed after three weeks. There was no peritonitis. There were traces of fat necrosis close to the ligature.

From the seventeen cats there were ten negative results. In two there were minute areas probably of fat necrosis. In five there was well-developed fat necrosis. One of the five exhibited disseminated fat necrosis. In detail, the operations and results were as follows:

Cat 11. Weight 6 lbs., 14 oz. The gastro-splenic portion of the pancreas was ligated. The animal was killed at the end of one week; weight 6 lbs., 5 oz. There was no fat necrosis nor peritonitis.

Cat 8. Weight 4 lbs., 1 oz., but fat. The gastro-splenic portion of the pancreas was ligated. The animal, while apparently healthy, was killed after one week; weight 4 lbs., 2½ oz. There was no peritonitis. Small nodules of fat necrosis were discovered at the interlobular pancreatic fat and in the omental fat. There was one nodule in the perirenal fat (Fig. 1), and one in the mesorectum. No bacteria could be demonstrated by staining methods in or near these areas.

Cat 6. Weight 7 lbs., 10 oz., well nourished. The gastro-splenic portion of the pancreas was ligated. The cat was killed after two weeks; weight 6 lbs., 15 oz. There was no fat necrosis nor peritonitis.

Cat 7. Weight 7 lbs., 4 oz., fat. The gastro-splenic portion of the pancreas was ligated. The cat was killed after three weeks; weight 5 lbs., 13½ oz. A few minute spots, probably of fat necrosis, were found in the omental fat. Staining methods showed no bacteria in or about them. There was no peritonitis. This was one of the two cases classed as doubtful.

⁴ Hildebrand: Centralblatt für Chirurg., 1895, vol. xxii, p. 297; also report Cong. Deutsche Gesellschaft für Chirurg., same journal. Dettmar: Inaug. Diss., Göttingen, 1895.

⁵ Jung: Inaug. Diss., Göttingen, 1895. Ref. in Centralblatt für Chirurg., 1895, vol. xxii, p. 310.

Cat 4. Weight 4 lbs., 8½ oz., poorly nourished. The gastro-splenic portion of the pancreas was ligated. The cat remaining healthy was killed after four weeks; weight 4 lbs., 2½ oz. There was no fat necrosis nor peritonitis.

Cat 3. Weight 6 lbs., 3 oz., fat. The duodenal portion of the pancreas was ligated. The cat was killed after one week, then seeming to be in good condition. There was no peritonitis. Traces of fat necrosis appeared close to the ligature. This was the second of the two cases classed as doubtful.

Cat 13. Weight 5 lbs., 15½ oz. Both the gastro-splenic and the duodenal portions of the pancreas were ligated, and as many as possible of the veins leaving the gastro-splenic portion were tied, and the continuity of the tissue of the pancreas was broken by a sharp hook passed into it beneath the peritoneum. The animal died after four days, being much emaciated. The autopsy was unavoidably delayed till about thirty-six hours after death. There was no peritonitis. There were several thin, flat areas of fat necrosis on the surface of the omentum. The mucous membrane of the pyloric end of the stomach showed a number of small round excavations having all the characteristics of peptic ulcers. All the peritoneal surfaces were abundantly covered with large bacilli, stained by Gram's method. No relation in their distribution to the spots of fat necrosis could be made out. Similar bacilli were present in large numbers on the mucous membrane of the stomach and duodenum, extending into the subperitoneal tissues and about the pancreas. In view of the long time that elapsed before the autopsy was made they were not regarded as of importance.

Cat 18. Both the gastro-splenic and the duodenal portion of the pancreas were surrounded with ligatures, as well as the veins leaving the former. The cat died after forty-eight hours. There was no fat necrosis nor peritonitis.

Cat 19. The operation and result were similar to those in Cat 18.

Cat 21. Weight 4 lbs., ½ oz. The gastro-splenic portion of the pancreas was ligated and as many as possible of the veins issuing from it, and the substance of the organ was broken with a hook. The animal died after four days; weight 3 lbs., 11½ oz. The autopsy was made in less than twenty-four hours. The peritoneal surfaces were covered with a fibrinous exudate. Beneath the peritoneal exudate a few thin, flat, white areas were seen, which proved to be necrotic adipose tissue. The exudate contained great numbers of diplococci and fewer large bacilli, both staining by Gram's method. The diplococci alone were recovered in cultures. They grew feebly, not liquefying gelatine, and very quickly died out. In sections, no grouping of the micro-organisms with reference to the spots of fat necrosis could be demonstrated.

Cat 22. Weight 4 lbs., 13½ oz., not fat. The gastro-splenic portion of the pancreas and the veins leaving it were ligated, and its substance was injured as in the other cases. The wound in the abdominal wall suppurated. The cat was killed on the fifth day after the operation; weight 4 lbs. At the autopsy, which was made immediately, the writer was astonished to find in the abdominal cavity a condition of disseminated fat necrosis comparable to that occurring in man. In the vicinity of the pancreas, the retro-peritoneal and omental fat was swollen, white and opaque, over an extent reaching twelve millimetres or more from the pancreas, and radiating from it in irregularly shaped masses. Smaller areas of similar character were scattered in great numbers through the omental fat and that of the mesentery along its entire length, even to the mesorectum. They occurred also in the perirenal fat. There was no peritoneal exudate. The animal was nevertheless the subject of an infection, proceeding no doubt, from the wound in the abdominal wall. The pus in this wound contained a variety of organisms, among them diplococci and large bacilli. Although examination of cover-slips was negative, cultures from the spots of fat necrosis and from the liver yielded diplococci or short streptococci, growing at room temperature, not liquefying gelatine, forming minute

white circular colonies on agar, and staining by Gram's method. Cultures from the pancreas and the blood of the right heart were negative. The distribution of the necrotic spots, especially of those in the mesentery, made them appear suspiciously like minute abscesses, but the microscope revealed their true character. In a section of the mesentery, diplococci were found in and about one of the areas of fat necrosis, and also, in smaller numbers, at points in the mesentery remote from it. Otherwise, the examinations of sections of the necrotic areas for bacteria were negative.

Cats 27, 29, 31, 32 and 36 were good-sized and healthy. In each case the splenic portion of the pancreas was constricted by a ligature near the duodenum, as many as possible of the veins leaving it were tied, and the tissue of the pancreas was disturbed as in the other cases. The animals all made good recoveries. Their abdomens were opened at periods varying from eight to seventeen days. There was no peritonitis, and no fat necrosis in any case.

Cat 34. Large and rather fat. The splenic portion of the pancreas was ligated near the duodenum, and the pancreas was then cut completely through on the distal side of the ligature, with the intention of allowing its secretion to flow into the peritoneal cavity. The animal died at the end of a week. The autopsy was made eighteen hours after death. The peritoneal sutures were found to have given way. The abdominal cavity contained a quantity of pinkish-white turbid fluid. The peritoneal surfaces were congested and covered with a thick layer of fibrin. The fat tissue of the omentum appeared swollen and edematous. Irregular white patches of necrotic fat tissue were seen in the omentum and in the vicinity of the splenic portion of the pancreas, especially near the cut extremity. Smears made from the peritoneal exudate showed it to contain many large bacilli, and minute cocci. Cultures made from the peritoneum, the viscera, and the blood gave only minute white colonies of diplococci, staining by Gram's method, lancet-shaped, and like the diplococcus of pneumonia in form. Sections of the necrotic fat tissue and of the pancreas exhibited great numbers of large bacilli and diplococci, by the Gram-Weigert method, mostly on the surfaces, and not showing any special relation to the areas of fat necrosis. Sections of the pancreas demonstrated necrosis of the fat cells about it and in the interlobular septa in a striking manner.

In all of the animals studied, the diagnoses were based on the microscopic examination of the tissues, which is indispensable. Many pictures of great beauty illustrating the condition were obtained. The tissues hardened in alcohol were found to be very well adapted for histological purposes. A five-per-cent. solution of formalin in normal salt solution preserved the macroscopic appearances more satisfactorily, but the writer has given up using it when the minute structure is to be studied. One-per-cent osmic-acid solution makes an excellent hardening agent, as the necrotic areas are not stained black by osmic acid. The areas of fat necrosis were sometimes rounded and nodular, about one to two millimetres in diameter; sometimes they were broad and thin. They occurred exclusively in the fat adjacent to the peritoneum, usually in immediate contact with it. A disposition of the necrotic process to affect the vicinity of the ligatures about the pancreas or the veins was noted, but it was not constant or very marked. In recently killed animals the recognition of the areas was easy, owing to their opacity, contrasting with the relatively transparent normal fat. When a peritoneal exudate was present, it was often difficult to recognize them beneath the layer of fibrin.

In frozen sections the areas were opaque, contrasting with the neighboring fat (Fig. 2). A brown tinge was often visible. Such complete disorganization of

Fig. 4

the adipose tissue as occurs in the human subject was in no instance observed. The areas consisted of rounded bodies similar in outline to the fat cells. In most cases the contents of these bodies were minute needle-shaped crystals. Frequently the crystals were arranged in a radial manner at the circumference of the circle. The central portion was then empty or contained oil droplets. Such bodies in transverse section appeared as rings (Fig. 4). Calcium salts were demonstrated in some nodules in abundance. The contents of the necrotic cells in balsam preparations usually appeared homogeneous, although their crystalline nature was sometimes discernible. They reacted variously with stains, in some instances showing an affinity for eosin, in others staining deep blue with hematoxylin. The more intense hematoxylin stain noted in some nodules the writer supposes to have been due to an abundance of calcium salts. The nuclei of the necrotic cells could not be identified. The amount of cell infiltration about the nodules of fat necrosis was quite variable. In some examples it was very slight, more often it formed a distinct band about the circumference where it was mingled with granules most of which stained deeply with nuclear dyes. Frequently it passed widely into the surrounding tissues. The cells were in large part polynuclear leucocytes. In part they were larger, mononuclear elements rounded or spindle-shaped in form, with round or oval nuclei. They generally were of moderate size, though quite variable in this respect. Fragmentation of nuclei was a prominent feature in this zone, the fragmentation being most extensive in the part immediately adjacent to the necrotic fat.

In and around the areas of fat necrosis numerous granules and rounded masses occurred, staining with carmine, hematoxylin, and by the Gram-Weigert method. Some of these were evidently fragmented nuclei; others were hyaline in character; others, which stained very deeply with hematoxylin, were supposed to contain calcium. These granules were often so numerous as to obscure the nuclei at the margin of the area. They rendered the search for bacteria in sections difficult and unsatisfactory.

The changes taking place in the pancreas were studied only with reference to the question in hand, and the account of them must be brief. The ligatures about the pancreas were found enclosed in a zone of leucocytes or good-sized mononuclear cells, or both, and often also of fibrous tissue. The cell infiltration frequently passed into the interlobular connective tissue of the pancreas and over its surface. In the animals that were allowed to live longest there were marked atrophy and induration of the ligated extremity of the organ, which the microscopic examination showed to be due to an atrophy of the acini and an abundant formation of fibrous tissue between the lobules, and even between the acini. Desquamation of the epithelial lining of the ducts was of frequent but not invariable occurrence. There was less dilatation of the ducts on the distal side of the ligature than one might have expected to encounter. The writer is unable to say with confidence that there was more interstitial pancreatitis or any other characteristic morbid condition of the pancreas in the animals that showed fat necrosis than in those that did not.

In nearly all cases sections of the liver, spleen and kidneys were examined, but no alteration was discovered that appeared to have any relation to the question

in hand. No tendency to hemorrhages of a marked or constant type was noted in any of the tissues. The urine was examined for sugar in the majority of cases, and none was found.

Although the writer has been less successful than Hildebrand, his work renders it evident that ligation of the pancreas in the cat may lead to fat necrosis. As far as he is aware, Cat 22 of his series exhibited the most extensive fat necrosis that has been recorded as having been produced by artificial means. The simultaneous existence of a diplococcus infection, in this animal and in Cats 21 and 34, is noteworthy. It is significant that the areas of fat necrosis were observed only in close connection with the peritoneal cavity, and especially in the neighborhood of the pancreas, which would make contact of the pancreatic juice with these areas intelligible. The circumscribed character which they usually exhibited and their occurrence at points remote from the pancreas are difficult to account for. It seems unjustifiable at present to say more than that extensive injury to the pancreas can cause fat necrosis.

The writer has been conducting experiments with a view to testing the direct action of the excised pancreas upon fat tissue. He believes that he has succeeded in producing fat necrosis in this manner. The conditions under which the change is effected are not yet clear, and any account of this work at present would be premature. A single one from this series may be related here, however, not to illustrate the direct action of the ferment artificially introduced, but to show the effects of a pancreatitis excited by accident.

Cat 15. Large and healthy. The abdomen was opened, a piece of pancreas 20 m. m. in length just removed from another cat was fastened to the omentum with a silk ligature, and the abdomen was closed. The animal died after six days. The autopsy was made twenty-four hours after death. A fibrinous exudate covered all the peritoneal surfaces. The effect of the piece of pancreas introduced upon the adjacent omentum was not clear. A small area of fat necrosis was discovered on the surface of the left kidney, and others were seen in the omentum. Section of the animal's own pancreas showed an acute pancreatitis, apparently originating by extension inwards from the infected peritoneum, which the exposed condition of the pancreas in the cat makes possible. Fat necrosis was seen in a large part of the fat tissue in immediate contact with the inflamed pancreas, and the connection between the two was demonstrated in a convincing manner. Cover-glass preparations, sections and cultures showed a large bacillus and a small diplo- or strepto-coccus, both staining by Gram's method, in the peritoneal exudate, and in the pancreas.

In this case, the conditions seem to be practically the same as those obtained by Hlava when pancreatitis and fat necrosis followed from the injection of the diphtheria bacillus into the pancreas. The possibility of their occurring ought to be borne in mind when pieces of pancreas or pancreatic extracts are introduced into the peritoneal cavity in experimental studies.

In connection with this work the writer has examined the pancreas and peritoneal adipose tissues of about forty cats. Quite early one was encountered exhibiting spontaneously minute white spots in the omental fat, not near the pancreas however, which on section resembled closely very small areas of fat necrosis. Recently a similar condition has been found in a second cat (Cat 37).

The animal was very fat. The abdomen was opened with a view to operating on the pancreas, when the adipose tissue of the omentum was observed to contain about ten irregular, opaque, white areas, approximately one-fourth of a millimetre in diameter. They were not observed in the vicinity of the pancreas. Two of these areas and a small bit of the pancreas were removed for examination, and the abdomen was closed again. Sections of the pancreas exhibited nothing remarkable. One of the suspicious areas in the omental fat, under the microscope proved to be opaque; after slight pressure it broke into irregular, translucent masses with a brown tinge, and made of fine, radiating crystals. Upon the warm stage, after the addition of glacial acetic acid, the brown masses dissolved; at the same time there was a noticeable evolution of oil droplets, apparently from the brown masses. The small size of the suspected areas made removal beforehand of the free fat with boiling alcohol and ether impossible. Subsequent neutralization and addition of oxalic-acid solution, produced an abundant precipitate of calcium oxalate crystals. Thin sections stained in hematoxylin showed the area partly surrounded by good-sized mononuclear cells, which, along with a small amount of fibrous tissue, partly penetrated its interior.

The condition seemed to be one of fat necrosis arising spontaneously in the cat and probably not recent (Fig. 3). If it depended upon any morbid state of the pancreas, that had apparently subsided. The animal made a good recovery. It is now, after ten weeks, still healthy. The intention is to observe the progress of events after the lapse of a longer period.

FAT NECROSIS IN THE PANCREAS OF THE HOG.

Balser,⁶ who was the first to describe fat necrosis in the human subject accurately, was also the first to study its appearance in the hog in detail. He found it in the fat tissue in or about the pancreas in nearly all Hungarian swine, frequently in Algerian, and in a few German swine. He found in the necrotic nodules bodies resembling the fungus of actinomycosis. In order to determine whether or not fat necrosis occurred in American hogs the writer examined the pancreas of one hundred hogs. It was impossible to learn anything more concerning the animals than that they were raised either in Ohio, Indiana, Illinois or Michigan, and were apparently sound and healthy. The pancreas of the hog is surrounded by a quantity of adipose tissue, which is also abundant between the lobules. The fat cells are very large. Little white flecks consisting of single fat cells or groups of fat cells are often seen in the pink parenchyma. Not rarely one meets with dark red spots in the parenchyma, several millimetres in diameter, apparently the result of hemorrhage. The organ, taken as fresh as possible, was cut in slices one to three millimetres thick, and each slice carefully examined. In two cases fat necrosis was found.

In one of these the number of areas of fat necrosis was not large and they were confined to a limited region. In the other they were numerous and were scattered throughout the organ. They were not conspicuous, being distinguished by their more yellow color, which contrasted with the white, normal fat. They appeared much like minute abscesses, but were somewhat harder than the normal fat. In shape they were irregular. Their various dimensions were one to two millimetres only. They nearly always impinged on one side against a portion of the parenchyma. Frozen sections showed them to be made of fat cells, rendered opaque by the presence of numerous needle-shaped crystals, frequently arranged in the form of a ring about

the circumference of the cell. They contained an abundance of calcium. Sections stained in hematoxylin and eosin gave about the appearances already described for the cat (Fig. 4). The contents of the areas exhibited usually a strong blue stain. The borders were surrounded by a band of connective tissue with numerous connective-tissue cells, and a small number of polynuclear leucocytes. Leucocytes also occurred in small numbers among the cells of the necrotic areas. Often they were in rounded clumps, corresponding to the outlines of a fat cell, and suggesting that they might have migrated into the interior of a necrotic cell. The ray fungus described by Balser after using the Ehrlich-Biondi stain was not found; nor were the hemorrhages about the necrotic areas. Examination of sections for bacteria was negative. Cultures were not made. The parenchyma of the pancreas was not remarkable. None of the other organs were examined.

SUMMARY.

Among two dogs, one rabbit and seventeen cats operated on in the manner described there were twelve negative, and three partly successful results. In five cases fat necrosis of a marked type followed. In three of the latter a diplococcus infection was associated.

A peritoneal infection in a cat was observed to lead to pancreatitis; which in turn produced fat necrosis.

Nodules, somewhat similar to those obtained artificially, which were seen twice appearing spontaneously in the omentum of the cat, were possibly old fat necroses.

Fat necrosis in and around the pancreas of the hog was found in two out of one hundred specimens examined.

EXPLANATION OF PLATES.

THE VALUE OF AUSCULTATORY PERCUSSION IN DIAGNOSIS.¹

BY ALFRED STENGEL, M.D., PHILADELPHIA, PA.,
Instructor in Clinical Medicine, University of Pennsylvania.

AUSCULTATORY percussion, or stethoscopic percussion, is by no means a recent addition to the methods of physical examination. It has been used by certain clinicians for many years, and I have myself employed it very largely during the last five years. For some time I have felt that its reliability and usefulness would warrant a more general application of the method, and have been led to summarize the conditions in which I have found it valuable.

I have been unable to learn by whom auscultatory percussion was first suggested and practised, and have little desire to make a search of the literature to determine this point. Da Costa, in his book on "Diagnosis," calls attention to the fact that it was employed by Cammann and Alonzo Clark, and the latter was accustomed to demonstrate it before his class. De Mussy described a method of *auscultation plessimétrique* in 1876.

¹ Read before the College of Physicians, Philadelphia, January 6, 1897.

⁶ Balser: Verhandl. d. XI Cong. f. innere Med., Wiesbaden, 1892, p. 450.

The methods themselves have varied somewhat as practised by different clinicians. De Mussy's method is as follows: The physician stands at the side of the patient and percusses over the upper dorsal vertebrae, the sternum, or clavicles, while the stethoscope is moved from place to place on the opposite side of the chest. Dr. Andrew H. Smith suggested the following method: The chest-piece of a binaural stethoscope is placed in the patient's mouth, and the lips compressed about it while the nostrils are compressed at the same time. The physician or an assistant then percusses the chest in various positions. Either of these methods may be employed to distinguish areas of pulmonary consolidation and the like; but their sphere of applicability is restricted even in thoracic diagnosis, and neither method is available for abdominal exploration.

My own experience has been with the simpler and more generally useful method of direct stethoscopic percussion of a certain organ. In the practical application of this method the chest-piece of a binaural stethoscope is applied to the surface of the body covering the organ under examination, and is held in place by the patient or an assistant. The examiner at the same time percusses lightly, using a pleximeter or the fingers alone, and approaching the supposed outlines of the organ from points at some distance. As soon as the outer limits of the organ over which the stethoscope is applied are reached, the ear detects a decided change of note. This change consists in an elevation of pitch and greater intensity of sound, and is recognized without any difficulty after a very little practice.

In suggesting his method of plessimetric auscultation De Mussy foresaw that objections would arise on the part of those who had not practised some such method, and who might be disinclined to investigate and acquire new modes of examination. This fear was well grounded, and objections have been urged, as I shall show below. It is well, therefore, to recognize in the beginning that auscultatory percussion embodies no really novel principle. We recognize by its aid exactly the same phenomena that occur in ordinary percussion, with the difference that the sound vibrations are conveyed directly instead of indirectly. In percussion of any organ or part of the body vibrations are set up that occasion certain sounds—resonant or dull, according to the state of the organ or the part examined. These vibrations are produced in the parts beneath the point of percussion, and are diffused more or less extensively, according to the nature of the parts and the strength of the blow. To a certain extent vibrations may be transmitted beyond the confines of the organs percussed, this transmission depending upon the distance from the limits of the organ at which percussion is practised, the strength of the strokes, and the nature of the adjacent organs. It is therefore difficult to determine the exact limits where the vibrations passing through the air are depeuded upon. Auscultatory percussion is useful in eliminating disturbing sounds and in allowing the recognition of vibrations emanating from a single part. In the following figure (Fig. 1) these points are graphically represented. The relative positions of the heart (*a*), lungs (*b*), and chest-wall (*c*) are represented, and the vibrations occasioned by percussion at various points are illustrated diagrammatically. When the pleximeter is placed at 1 the vibrations are confined to the chest-wall and the lung-tissue, and the clear note of pulmonary resonance is obtained. When the per-

cussion is practised at 4 the dull sound of the heart is noted. At 2 vibrations arise that involve the lung-tissue to a greater and the cardiac to a lesser degree; while at 3 the reverse obtains. In either case it is difficult to determine precisely whether the note is that of cardiac dullness or pulmonary resonance. The difficulty is to a large extent removed by the simultaneous use of the stethoscope. If the chest is placed at 4, for example, and percussion is practised at 1, no vibrations, or at most distant ones transmitted through the lungs or chest-wall, are recognized. When percussion is carried to 1' the sound becomes louder, but still indistinct. Only when the point 2 is reached, and the percussion-stroke is directly over a part of the heart (even though a thin edge of lung separate the heart from the chest), is the sound obtained, immediate and clear. Even with this method there must be a certain amount of error in determining the limits of certain organs, like the heart, which slope away from the chest-wall; but the error is much less than with ordinary percussion.

FIG. 1. Showing diagrammatically the distribution of vibrations caused by percussion over the heart and lung.

Care must always be taken to place the patient in such position as to relax the superficial parts, and thus eliminate the vibrations transmitted through the fasciae and muscles.

In the practical application of the method I have repeatedly satisfied myself of its superiority over ordinary percussion in cases in which an experienced diagnostician could readily use either method. In my demonstrations to students, for example, I have frequently marked the limits of the heart by ordinary percussion, and then allowed the students to determine the limits by auscultatory percussion, keeping their eyes closed while I percussed lightly. The accuracy of the results have been very striking, and contrasts strongly with the variability in the outlines voices obtain from ordinary percussion of this organ.

Objection has been made to this method by a number of writers, some of whom have evidently practised it but little. I wish only to allude to the criticism of Dr. Herschell. This observer found that the change of note occurred when the pleximeter was brought within a certain distance from the chest-piece of the stethoscope, the distance being equal on all sides, and therefore in no way dependent upon the underlying organs. Mr. Bezly Thorne has adequately answered this criticism, which manifestly rests upon insufficient observation; but I have repeatedly demonstrated the unsoundness of Dr. Herschell's view in a practical way to the satisfaction of students and others inexperienced in this method. I have, for example, placed the chest-piece of the stethoscope over some part of an organ near its periphery (as over the heart, at *A*, Fig. 2), and outlined the organ, finding the same change of

note when the percussion reached the limits of the organ near the stethoscope as that occurring when the pleximeter reached the periphery of the organ most distant from the stethoscope. I have then placed the stethoscope at a distant part of the organ (as at *B*, Fig. 2), and found that the limits determined by the percussion were exactly the same as before. This practical demonstration that the change of note is dependent upon the underlying organ, and not upon the mere distance of the pleximeter from the stethoscope, is convincing, and I do not therefore find it necessary to invoke theoretic considerations in explanation or defence of the method. It may, however, be well to explain, as Thorne has done, that there is a certain amount of vibration of the chest-walls themselves which will reach the stethoscope from variable distances surrounding the stethoscope, and that these become audible when percussion is practised within this area. A very little experience, however, will teach us to distinguish between such a change of note and that arising from vibrations in the deeper structures.

FIG. 2.

Very recently a method has been proposed by Bianchi and Compté, in which the phonendoscope of the former observer is employed. This instrument is a modified form of microphone, in which the vibrations over the chest are transmitted directly or through a metal stem to a system of ebonite plates, and from these through rubber tubing, as in the ordinary stethoscope, to the ears.

The instrument itself has certain advantages in conveying faint sounds very clearly to the ear, and it may be employed as the ordinary stethoscope. I have, however, found little advantage over the binaural stethoscope and several disadvantages. The pressure necessary when the metal stem is used is such that at times, with the small size of the button upon the metallic stem, considerable pain or discomfort is occasioned; and when the stem is not used the instrument covers too large an area. In young children I have found it practically impossible to use the phonendoscope with satisfaction on this account. It was hoped from the magnification of the sounds obtainable with this instrument that it would prove especially useful in auscultatory percussion, and Compté in particular described a method of procedure for which he claimed brilliant results. The button of the phonendoscope, according to this method, is placed over the organ to be examined, and the ear-pieces are adjusted, whilst the finger is drawn over the skin, beginning at the point where the button is applied and running outward in radiating lines from this to the centre. As soon as the finger passes beyond the limits over which the button is

placed it is claimed that the rasping bruit heard before suddenly ceases. This change of note is described as being very abrupt and distinct. In my experiments with this method I have uniformly found that such was not the case. The note does suddenly change when the finger has passed to a certain distance from the button of the instrument; but this distance is equal more or less, in all directions, and it seems to me easy to explain this fact. The vibrations occasioned by the finger drawn over the skin cannot manifestly occur in the deeper tissues or organs, but only in the skin and the immediately subdermal tissues. It is quite improbable, therefore, that the position of the deeper organs would have any influence upon the sounds obtained through the instrument, and it is altogether probable that these sounds would be greatly influenced by the distance to which the finger is carried from the instrument. This distance, of course, represents that to which vibrations in the skin are readily transmitted. The method of Compté is therefore, I believe, wholly useless. The phonendoscope itself may be employed for auscultatory percussion after the ordinary method; but I find no advantage here over the ordinary stethoscope, and perhaps the loudness of the sounds may in some cases prove an actual disadvantage.

I wish now to consider somewhat in detail the value of this method in the examination of the different organs.

THE HEART.

In applying auscultatory percussion to this organ I am accustomed to place the stethoscope near the apex and then to mark the limits on all sides by percussing lightly and then heavily, but always with strokes of equal force in each separate determination. The lower border, where the left lobe of the liver and stomach lie adjacent, is usually determined with great precision, and the same to a slightly less extent may be asserted of the oblique border and the apex where the change of note in passing from the lung to the heart is usually quite distinct. The upper limit, particularly that immediately beneath the sternum, is more difficult to determine accurately on account of the more ready transmission of vibrations through the sternum and ribs. In persons with emaciated thoraces, and particularly in those in whom the sternum bulges forward, the difficulty may be very great; but I have never as yet failed to determine with measurable satisfaction what seemed to me to be the limits of the organ in this direction. It will in difficult cases be necessary to percuss a number of times and with varying force before a conclusion is reached; but when the practical impossibility of determining by ordinary percussion the position of the upper border in the cases here alluded to is considered, the advantages of the stethoscopic method must be admitted to be very great. Thorne contends that the note over the great vessels at the base of the heart (the aorta and pulmonary artery) may be distinguished from that of the heart, and that a bipartite outline of the organ, due to the auriculo-ventricular groove, may be determined. These claims seem to me somewhat too extravagant; and though I am prepared to admit that some distinction may at times be noted in normal cases between the sound heard when percussion is practised over the vessels and that audible when the heart itself is percussed, I have never been able to draw sharp lines and cannot pretend to distinguish the position of the auriculo-ven-

tricular furrow. In some few cases of enlargement of the aorta in aortic valvular disease, and still more in cases of aortic aneurism, I have found separate areas, such as those represented in Figs. 3 and 4.

The right border of the organ above the hepatic dulness is usually easy to determine, though there is some difficulty in emaciated persons. Projection of the right auricle beyond the right border of the sternum is discovered in many normal individuals, though by no means in all. The inferior border on the right side, where the heart and liver are adjacent, is somewhat difficult when the ensiform cartilage and the ribs are closely approximated and projecting, but as a rule little difficulty is encountered. Ordinary percussion may in some cases suffice to determine where cardiac dulness ceases and the hepatic begins by the change of note detected; but there can be no comparison in accuracy between the older method and stethoscopic percussion.

I have not preserved sufficient records of the exact outlines of the heart obtained in normal cases to state

FIG. 3. Mitral and aortic disease, showing distinct area of aortic enlargement. The line of demarcation between aortic and cardiac dulness was not as distinct as the diagram would suggest, but was undoubted.

the limits in health, but have repeatedly noted that the area is greater than that obtained by ordinary percussion. The right border frequently extends beyond the right side of the sternum, as I have said before, and the left border as far to the left as the nipple-line; the base is found as high as the second interspace in many instances.

Besides the greater accuracy obtained by this method of exploration in ordinary cases it may be mentioned that in emphysema of the lungs stethoscopic percussion often proves satisfactory when the older means of examination are useless. In cases of moderate marginal emphysema, of malformation of the lungs, or of abnormal lobulation or retraction of the anterior portions of the lungs, in which the heart is either excessively or insufficiently covered by the lungs, a comparison of the extreme limits obtained by auscultatory percussion with those determined by the ordinary method may clear up conditions not otherwise discoverable. Finally, an advantage of this method is found in children or sensitive adults in whom it is undesirable to use force in striking the chest, and in whom, therefore, ordinary percussion is unsatisfactory.

My experience with auscultatory percussion in pericardial disease is limited to a few cases, and I can merely state that it commends itself on account of the early discovery, possible by this means, of dulness on the right side of the sternum. The liquid collects in the

pericardial sac surrounding the right auricle quite early in the disease, but may for some time occupy only the posterior part of the pouch. Auscultatory percussion will determine such effusion much sooner than the ordinary method.

LUNGS AND PLEURA.

The spongy structure of the lung renders this organ less satisfactory for the application of the method under discussion. It is possible to limit areas of consolidation with accuracy when they are considerable in size, but in this respect the method has little advantage over simple percussion. When the areas are small and the consolidation merges gradually into the normal pulmonary tissue, auscultatory percussion is unsatisfactory. I have not found the method of material assistance in cases of beginning consolidation of the apices. In these cases so much disturbance may be occasioned by varying conditions of the bony framework, by the force of the percussion-strokes and other factors that I should hesitate to accord it special advantages in diagnosis. In cases of large

FIG. 4. Aneurism of the arch of the aorta, showing distinct area of dulness. The line of separation was sharply marked.

cavities I have found stethoscopic percussion useful, though but little more satisfactory than ordinary percussion. When there are small cavities these may at times be localized by placing the stethoscope over a somewhat removed portion of the lung and percussing near the supposed situation of a cavity. There will be found quite a marked reduction of sound when the percussion passes from the healthy or consolidated lung to the area of evacuation. Unfortunately, the consolidation surrounding small cavities is usually so dense or extensive that vibrations emanating from this source interfere with the nicety of the method.

A great advantage is found in cases of consolidation of the bases when it is difficult to determine by ordinary methods to what extent dulness is due to hepatic or splenic enlargement or to pulmonary consolidation. It is true, of course, that the spleen and liver, as a rule, become displaced or enlarged in a downward rather than an upward direction; but still there are cases in which the question of the upper limit may be difficult to determine. In such instances the stethoscope may be placed over the liver and the upper border of this organ determined; then over the lung and its lower limit defined. I have found this mode of examination useful in several cases, particularly in one of great hepatic enlargement in a rachitic child recently under my care.

In case of thickening of the pleura the extent of the area of involvement may be determined by this

method, though there is no material advantage over ordinary percussion. In cases of pleural effusion, however, the upper limit of the liquid is easily determined, and, as has already been indicated in speaking of the delimitation of the liver and of pulmonary consolidation, auscultatory percussion has special value in permitting a ready distinction between the dullness of the pleural effusion and that of the subjacent liver. I conceive that in cases of interlobular pleural exudate the outlines of the area of dullness might be more easily determined by this method than by ordinary percussion, but have had no experience in this matter. It is possible, also, that auscultatory percussion may prove of some value in distinguishing between obscure cases of subdiaphragmatic collections of pus and pleural effusions by revealing, on the one hand, a gradual increase in the intensity of the note heard with the chest-piece of the stethoscope over the liver while percussion is carried downward toward the liver, this gradual increase in sound being explained by the transmission of vibrations to the liver from the liquid

FIG. 5. Showing the extent to which the liver and lung cover the stomach normally, and the relation of the colon to the greater curvature. (Modified from Lushka.)

immediately above it, while in pleural effusion a sharply defined line would be obtained as soon as percussion was carried below the diaphragm and to the upper border of the liver. This, also, is purely speculative, as I have had no occasion to test the matter in practice.

THE ABDOMINAL ORGANS.

While the advantages of the method under discussion are sufficiently great in the diagnosis of thoracic diseases to warrant its more general adoption, I have found it particularly serviceable in obscure abdominal affections and as a routine method in examination of the stomach.

THE STOMACH.

The unreliability of direct percussion of the stomach need not be considered at length. It may be said, however, that among the conditions which render it inadequate are the extent to which the left lobe of the liver covers over the lesser curvature and upper part of the organ, the fact that a large part of the body is concealed by the ribs on the left side and covered over by the arch of the diaphragm, and by the fact that not rarely a distended colon or one containing fecal matter may remove the lower part of the organ from the abdominal walls and render percussion uncertain. Auscultatory percussion has the advan-

tage that it is rarely difficult by firm percussion and by repeated trial to distinguish the limits of the organ even beneath the thin portion of the liver that usually covers it over. The same may be said of the portion of the stomach covered by the lung, diaphragm and ribs, and, to a lesser extent also, of the inferior border where clonic distention ordinarily interferes (Fig. 5).

The routine employment of this method in the examination of the stomach of many patients has convinced me that its advantages in the recognition of the size of this organ are second only to those of direct inflation with atmospheric air or gas. It is practically always possible to determine the lower border of the organ, the position of the fundus, and of the lesser curvature. From these data the probable size and position may be determined with considerable certainty.

In the accompanying diagram (Fig. 6), representing the outlines of the organ as determined by stethoscopic percussion in a case of carcinomatous stenosis of the pylorus, the positive demonstration that these

FIG. 6. Carcinoma of the pylorus, showing the outline of the stomach obtained by auscultatory percussion; confirmed by inflation.

outlines were correct was furnished by subsequent inflation of the organ with the aid of a stomach-tube and the bulb of a Davidson syringe. It will be readily seen from the diagram that the lesser curvature was considerably depressed below its normal position, so that an explanation was readily obtained for the depression visible in the epigastric region. At the first examination of this particular case the great enlargement of the organ was not discovered, and I was inclined to attribute the failure to the method, whereas it was subsequently discovered that this failure was attributable rather to hasty examination. In an examination of the patient the chest-piece of the stethoscope was placed over the position of the normal fundus and percussion was made from a point just above the umbilicus toward the inferior margin of the left ribs. Gastric tympany was not obtained until the point A was reached, and it was erroneously inferred that the organ was rather small than large. Subsequent examination showed the outlines in the diagram. The determination of the upper curvature by this method is of particular advantage in distinguishing cases of gastroparesis and gastric dilatation. In the case of tumors of the pyloric region it is generally possible to determine that the neoplasm is connected with the stomach, and thus an aid is afforded to the differential diagnosis between gastric tumors and tumors of the

gall-bladder. The determination of this point is accomplished by placing the stethoscope over the body of the stomach and carefully percussing toward the tumor from all directions. The note obtained from the tumor may be quite different from that found over the uninvolved portions of the organ, but it will be noted that the tone over the tumor is much more nearly like that of the stomach proper than that found in the surrounding parts. The diagram (Fig. 7) represents a case of neoplasm of the liver in which the test just alluded to was made, and served to indicate that the tumor was situated away from the stomach, this being confirmed by inflation of the stomach and subsequently by exploratory incision.

Great advantage may be obtained by combining inflation with auscultatory percussion, in which case the exact limits of the organ are usually obtained with very great ease. As a rule, however, inflation is unnecessary, and in routine practice is undesirable.

INTESTINAL DISEASES.

It is possible at times to determine the exact course and size of the colon by this method, providing, of course, that the bowel is empty and well inflated.

FIG. 7. Tumor of the liver. Outline of stomach determined by auscultatory percussion.

Lavage and partial inflation may be practised previous to the examination in cases of particular interest. I have found, by placing the chest-piece of the stethoscope over the caput coli and percussing over the centre of the abdomen toward either side and toward the epigastrium, that the inner limit of the large bowel could often be determined; and subsequently, by percussing from the extreme flanks and from above toward the middle of the abdomen, the outer limit of the ascending, descending, and transverse colon could be determined. If the small intestines are greatly inflated, however, it is scarcely possible to distinguish sharply between the note of the small and large bowel. In one case I was able to determine that a tumor occupying the left flank was connected with the descending colon, and in another instance located a carcinomatous mass at the hepatic flexure by this method. In these instances the limits of the colon were first determined and the tumors referred to were found to correspond to the course of the gut; then careful percussion was made over the tumor and toward it from all sides with the stethoscope over the adjacent but uninvolved part of the bowel. Finally the stethoscope was placed over the tumor itself and percussion directed toward the intestine near by. The result of all of these procedures showed plainly that the tumors involved the bowel walls.

THE LIVER.

The exact limits of this organ are easily determined, as a rule, by this method, and neoplasms directly connected with it are readily distinguished from tumors of adjacent viscera which occupy a position near to the liver, but unattached to it. The example already alluded to of a neoplasm of the lower edge of the liver serves to indicate the advantage of the method in distinguishing the exact seat of such growths. When adhesions have taken place between the liver and tumors of the neighboring organs, particularly of the stomach, and especially when the tumor has infiltrated the liver-substance and a confused mass of neoplasm is thus established between the originally involved organ and the liver, greater difficulty is experienced, and, as a rule, it is impossible to determine whether the seat was primarily in the substance of the liver or in an adjacent organ. As an instance of this I may cite a case of carcinoma of the pylorus and lesser curvature of the stomach which had become connected with the left lobe of the liver and in which auscultatory percussion determined a gradually diminishing note toward the stomach and toward the liver. It was impossible to determine which organ the disease had invaded most extensively. In cases of neoplasm of the body of the gall-bladder and in case of empyema or dropsical swelling of this sac the distinction from new growths of the stomach or from movable kidney may sometimes be possible. I have found it so in several instances of moderate enlargement of the gall-bladder; but must admit that in cases of greater enlargement of the gall-bladder difficulty would probably be experienced, since the vibrations would not be transmitted to the liver when the neck of the gall-bladder or the pedicle of the tumor, so to speak, is much attenuated. Unfortunately, I have had no opportunity to examine such a case by this method.

THE SPLEEN.

Greater exactness may be obtained in determining the limits of this organ by auscultatory percussion than by the ordinary method; but I am not as yet convinced that it possesses sufficient advantages to determine in all cases by this method alone whether the organ is enlarged or not. So much depends upon the exact position of the organ, whether it projects against the chest-walls with the narrow edge or the broader side, and upon other conditions, that I am unwilling to assert that it is possible to determine, from the percussion limits, whether the organ is normal or somewhat enlarged. Of course, in cases with great enlargement auscultatory percussion will be found satisfactory, but it may be said that ordinary percussion is available in the same cases. After all, a combination of palpation with percussion should be relied upon rather than either method alone.

THE KIDNEYS.

In several cases of pyonephrosis I have found that the enlarged organ could be readily outlined by stethoscopic percussion; but in these cases palpation and even inspection of the back with ordinary percussion were almost as satisfactory. The only advantage obtained was that of a greater feeling of security in ascertaining the enlargement of the affected organ.

I have met with no case of moderate enlargement of one kidney in which I have been able to assert

from the use of this method that the organ was enlarged when the ordinary methods of examination had failed to reveal any enlargement. It is not impossible or improbable, however, that such border-line cases may be discovered now and then.

In practising the method upon the kidney the greatest possible attention to certain details is necessary. If a patient is standing in an erect position, the large lumbar muscles are so stretched and prominent that the vibrations obtained from these will overshadow any that might be obtained from the deeper-lying organs, and I have found that it is practically impossible to determine with any degree of satisfaction the position of the kidneys. The same may be said of the prone position in bed unless the patient be placed upon a number of pillows heaped up so that the back is somewhat arched and the muscles are entirely relieved of any tension. A more comfortable position, however, is one midway between the prone and the lateral position. The patient is placed in this posture and the physician stands at his back and is then able to examine the kidney of the opposite side from that on which the patient is lying, with a fair amount of certainty in the results. On the whole, however, I have obtained no striking results in the examination of the kidneys.

Clinical Department.

MASSACHUSETTS GENERAL HOSPITAL. CLINICAL MEETING OF THE STAFF.

J. COLLINS WARREN, M.D., SECRETARY.

REGULAR Meeting, February 10, 1897, the President, DR. CHARLES B. PORTER in the chair.

The following cases were reported, the patients, specimens and photographs being shown :

TYPHOID FEVER, WITH PERFORATION.

DR. F. C. SHATTUCK: A Harvard student, nineteen years old, entered my service on the 22d of October. For ten days he had had malaise, headache, lack of energy, etc. Four days before entrance he went to bed, with frontal headache as the most troublesome symptom. On entrance physical examination was practically negative. The diazo-reaction was present in the urine; no leucocytosis; 6,500 white cells; no plasmodia in the blood. He came from New Jersey, and we thought of malaria. No rose-spots. On the 25th rose-spots appeared. It was a mild case. There was not the slightest symptom to cause uneasiness. On the morning of the 26th, at my visit soon after eleven o'clock, I noticed that he looked somewhat distressed, and he said that pain in the belly had just come on. The bowels had not moved for two days, and I supposed that the pain was probably due to wind or constipation. I gave an order that he should have an enema and, if necessary, later a hypodermic of morphia. An enema was given, with fair results, though he could take only about a half-pint. He had a hypodermic at one o'clock. In the evening, about seven o'clock, they telephoned that he was much less well. The pain was persistent and the pulse had gone up. At 8.30 Dr. Porter and I held a consultation. It seemed clear that he had a perforation. He

had been doing absolutely well, and this pain had come on very suddenly in a perfectly unaccountable way. The face was anxious, rather pinched; and the change in less than twelve hours was very striking indeed. The white count had gone to 14,700 from 6,500 on entrance. The first symptom being on the 9th of October and this on the 26th, there were only seventeen days from the first suggestion of his being ill, and less than ten days from the time he took his bed. We had the advantage of a young man in first-rate condition, with a mild process which had not greatly impaired his resistance, and we also had the advantage of having got the perforation pretty early: the consultation was within twelve hours after the first symptom suggestive of its occurrence. I will leave the rest of the case to Dr. Porter.

OPERATION FOR INTESTINAL PERFORATION IN TYPHOID FEVER.

DR. C. B. PORTER: On October 26, 1896, an incision, five inches long, passing to the left of the umbilicus, was made. Some turbid serum escaped, but no fecal matter was seen. The odor was slightly fecal.

The coil of distended intestine which bulged out through the wound was carefully examined, and was gradually drawn out, being replaced as fast as examined. The duodenum was finally reached without finding a perforation. From this point the small intestine was systematically examined. At the lower portion flakes of fibrin were found on the bowel, and in one or two spots the intestine looked as if ulcers were on the verge of perforation. Finally, near the cecum a sloughing area was found on the peritoneal surface from which gas bubbled. No fecal matter was seen. There was an indurated thickened area around the perforation. Intestinal sutures were placed in a diamond-shaped area, the line of the stitches being transverse to the axis of the bowel. The ulcer was turned in, the peritoneal surfaces being apposed over it. A second row of sutures was placed, covering the first row, and the bowel was replaced. The abdomen was thoroughly wiped out, and a drainage-wick was put into each side of the pelvis.

The pulse was 150, and of poor quality after the operation. Under stimulation and the use of salt solution by enema and subcutaneous injection the pulse fell to 120, and the patient came out of the ether fairly well, and seemed to feel better than before the operation, the acute pain being relieved.

October 27th. On the day following the operation the patient steadily improved. There was nausea and the regurgitation of small amounts of brownish fluid, but no real vomiting. At night the pulse was full, regular and strong, about 110. The temperature was lower than before the perforation.

October 28th. The patient spent a very restless night and was delirious. He seemed to be less nauseated than on the day before, but was unable to take anything by mouth. Pulse very good and regular. Patient seemed to be holding his own. The abdomen was much distended. The wound was draining well. In the evening he vomited, and passed much gas and a little fecal matter. After enemata of sulphate of magnesia, aloes and turpentine, the abdominal distention decreased markedly.

October 29th. On this day the pulse became very weak; and notwithstanding stimulants and salt solu-

tion enemas the patient failed rapidly, and died at 11.45 A. M., sixty-one hours after the operation.

AUTOPSY ON ABOVE CASE.

DR. J. H. WRIGHT described the autopsy, made October 29th.

The body is that of a young man of good height and good osseous development, but rather emaciated. In abdominal wall, beginning about three centimetres above umbilicus, and extending downward slightly to left of same for a distance of about twelve centimetres, is a linear wound, closed above with sutures, its lower portion packed with gauze. Incision restricted to abdomen and lower portion of thorax. Rigor mortis not marked. Slight post-mortem discolorations. Subcutaneous fat small in amount. Intestines distended and rather firmly bound together, and adherent to anterior abdominal wall about wound by a rather thick, grayish-yellow, dry exudate. Serous surfaces injected. Little or no fluid.

In the ileum, about thirty centimetres above ilio-cecal valve, there is a row of black silk sutures extending around two-thirds of the circumference of gut, and binding the serous surfaces firmly together. The wall of the gut has been folded in upon itself in such a manner as to bring the adjacent serous surfaces together. On the mucous membrane beneath the row of sutures is an ulcer about nine millimetres in diameter, with elevated, smooth margins, somewhat undermined, and with a fairly smooth base. The lumen of the gut opposite the ulcer is diminished by about one-half, and is choked with a rather firm, dry, putty-like fecal mass, which seemed to be moulded into the narrowed portion. Pressure upon the unopened gut in the neighborhood of the sutures shows no leakage, but firm union. The ileum below the sutures shows perhaps a half-a-dozen ulcers, the largest about one centimetre in diameter. These have smooth, clean bases and elevated, somewhat reddened, smooth margins. One ulcer extends to peritoneum, and its base is formed by the serosa. The mesenteric glands adjacent to ulcerations, enlarged, reddened with grayish-white mottlings. The remaining mesenteric glands slightly reddened and not enlarged. The large intestine is not especially affected. The jejunum, over a space of about four feet, shows extensive irregular areas in its mucous membrane, black-red, and dirty-yellowish-gray in color. The black-red color seems to be due to hemorrhage into the tissue, while the grayish color seems to be due to a necrotic or degenerated condition of the mucous membrane. No definite ulcerations. The external appearance of the intestine beneath these areas in some cases is dark red, in others not.

The spleen shows a large, gray-red, mottled, hard, irregular, projecting area, about the size of a five-cent piece. On section this is seen to correspond to one or two confluent, firm, slightly yellowish, irregularly outlined, sharply defined areas in the spleen-pulp. Another similar area, the size of a large pea, also present. Length, twelve to thirteen centimetres.

Heart. Normal. Muscle firm and in apparently good condition. No fluid in thorax or pericardium. Lungs normal, except for small scattered dark-red areas in parenchyma. Some old adhesions on left lung.

Aorta. Smooth.

Liver. Rather gray and opaque on section.

Kidneys. Rather pale. Cortex, seven to eight

millimetres. Capsule easily removable. Markings distinct.

Bladder small and contracted.

Anatomical diagnosis. Typhoid ulceration of ileum at stage of about latter part of third or the beginning of fourth week. Acute general fibrinous peritonitis. Intestinal suture for perforating ulcer. Stercoraceous inflammation of jejunum. Acute degeneration of liver and kidneys. Infarctions of spleen, probably due to thromboses of small splenic arteries.

DR. C. B. PORTER: I would like to say with regard to something omitted that none of the sutures were tied until they were all in place, and then tied from each end towards the middle of this area. It was because the thickening from the indurated base of ulcer would not allow of turning in in the centre, but finally starting at the two ends that was accomplished.

It seems to me that the element of obstruction entered into the final cause of death, as well as a certain amount of sepsis of the abdominal wound, and it seems to me that if we had not been afraid of injuring the part that had been sutured and had made the stools liquid, this obstruction might not have taken place.

DR. BEACH: I should like to ask what Dr. Porter would have done if he had found fecal extravasation.

DR. PORTER: I think I should have irrigated the whole abdominal cavity and done intestinal suture.

A CASE OF FRACTURED PATELLA; WIRING THE FRAGMENTS.

DR. C. B. PORTER: It is still a question as to the desirability of wiring fractured patella, and I think that we have not arrived at a final decision in the matter. This man had a fracture that had existed eight months and a separation of the two fragments amounting to three and a half and four inches, and he was absolutely incapacitated. The fragments had been separated from the first, showing no tendency to fibrous union and no attachments at all except by the skin. Having cut down and refreshed the edges I put in very strong silver wire and with the assistance of Dr. Newell I endeavored to bring these fragments together. I finally cut the rectus and part of the vastus internus and divided certain of the deeper bands and at last, after nearly an hour of pulling and resting alternately we got the fragments together and he has a perfect union. The exceptional thing about it is in the division of such masses of muscle to bring the fragments together, and another exceptional thing we could not have expected in the old treatment is union by first intention of both wounds.

HEMANGIOMA OF THE BUCCAL POUCH, TWO CASES.

DR. J. C. WARREN: These remarks refer principally to two cases of what I have described as hemangioma of the buccal pouch, a form of tumor I do not remember having seen before in that situation, and curiously enough both came into the hospital at the same time. Both young women, eighteen and twenty-four. Both had precisely the same thing appearing on the left cheek. The tumors were lobulated, feeling like lipomata, about the size of a hen's egg and of the substance of the cheek, deeply situated. On consultation it was decided they might be, the first at all events, lipomata or possibly obstruction of the duct of Steno by a salivary calculus. The patients were both operated upon by the same method, — a vertical in-

cision to the mucous membrane of the duct on that side. Introducing the finger through this incision the tumor was isolated from its surroundings which were very loose. It was then forced out through the cut made in the cheek and its attachments tied and removed. They both turned out to be plexiform angioma, a coil of small blood-vessels. One healed with some suppuration and the other by granulation without any incident worthy of note.

REPORT ON THE ABOVE TUMORS OF THE BUCCAL POUCH.

DR. WM. F. WHITNEY reported as follows:

(1) The tumor was an irregularly flattened ovoid mass measuring one and one quarter by one by one-half inch. It was imbedded in fat tissue into which it passed without any distinct line of separation. The section surface showed an alternating fatty and fibrous aspect, the latter further marked by very small irregular dark-red areas, in places of a decidedly fine spongy texture.

FIG. 1.

Microscopic Examination. — In the outlying fat tissue were dilated veins filled with blood and about them the connective tissue was increased slightly. The central part was composed of a meshwork of fibrous tissue in which were scattered small bundles of smooth muscular fibres, the inner surface was covered with a thin endothelium. The spaces thus formed were filled with blood. In places the walls were thin and very fibrous, the spaces large and subdivided by partial partitions. In others the spaces were circular and the walls about thick and evidently of vascular origin. On the periphery were numerous small thick-walled vessels (arteries).

Diagnosis. — Cavernous and telangiectatic hemangioma.

(2) A firm, rounded mass, three-quarters of an inch in diameter, imbedded in fat tissue. Section surface variegated by small dark red areas separated by greyish and more translucent ones, giving to it a finely marbled appearance.

Microscopic Examination. — It was seen to be composed of vascular, fibrous and fat tissue. In places there was no question but of dilated vessels with thick

walls. One such was seen, irregularly dilated, giving off side branches for some distance and then suddenly expanding into a cavernous space with sinuous walls, well supplied with smooth muscular fibres. Elsewhere the structure was cavernous, with thin, fibrous partitions, from which were papillary-like projections forming partial subdivisions. Among these essentially fibrous and vascular parts was scattered fat tissue.

Diagnosis. — Telangiectatic and cavernous hemangioma.

OSTEO-MYELITIS OF THE HUMERUS.

DR. J. C. WARREN: The next case is one of common type, and that is the reason I decided to show him to-night, a type of disease which I think often goes unrecognized. Here in the hospital we see the results, not the primary symptoms. I refer to osteo-myelitis. I have said so much about this that I feel a little hesitation about speaking of it. It is, however, one of practical interest, and ought to be brought to the attention of the staff, owing to the difficulties of diagnosis

FIG. 2.

in the early stages and the very serious results which follow a neglect to operate in time.

This boy is seventeen years of age; and when you look at him you will think he is a good deal younger; he is a delicate subject. He worked hard in a clothing store at the North End; and about three weeks before his entrance to the hospital in Dr. Shattuck's ward he was taken with a chill and symptoms of acute rheumatism, and was treated for this by his physician from whom I had a verbal account of the case. He had swelling and tenderness of his left shoulder and (these are points I hope the gentlemen will keep in mind) apparently an acute rheumatic affection of his right knee and left ankle also. He was treated for rheumatic fever, and the swellings in the knee and ankle subsided, but remained in the shoulder; and then he was sent to Dr. Shattuck's ward. Shortly after that the skin reddened, and fluctuation was detected by Dr. Shattuck, and the case was referred to me. I made the diagnosis of acute osteo-myelitis of the head and shaft of the left humerus, and a day or two later performed an operation, a diagram of which is here sketched by Dr. Mosier (Figs. 1 and 2). There was

a vertical incision made through the deltoid muscle, and a large quantity of pus was allowed to escape. In the centre of this abscess, standing like a pillar, was the bone, somewhat but not entirely denuded; and here is where I wish to make a point. Many surgeons would be satisfied with making a free incision like that into the abscess cavity, but those familiar with the peculiarities of this disease would recognize that this was only the outer area of infection, and that the primary focus was seated in the bone itself, in the interior. Consequently, a channel was dug out with the chisel and mallet from the head of the humerus above the epiphyseal line about one-third way down the shaft. Very characteristic appearances were found inside the bone — purulent infiltration, breaking up of the spongy part and thinning of the cortical bone. Several small sequestra were removed. The trough thus made was washed out with carbolic acid and other disinfectants, and the wound, which is shown in the second diagram, was filled with iodoform gauze, and the edges brought together. The boy has been convalescing since, and the temperature, which was high, has subsided.

The points I wish to bring out in this case are the fact that in the early stages of this disease the affection resembles so closely articular rheumatism; the subsequent early operation before general extensive necrosis of the bone had come in and an involucrum had formed, and, consequently, cutting off that period which develops in this disease and which is so slow in working itself out, namely, the formation of the new bone around the dead bone and the gradual separation of the sequestrum.

The subsequent history of this boy will be interesting. It will be interesting to see whether or not his disease has not been shortened by nearly a year by this operation. Here is the boy. The wound is healing readily. He has gained a good deal of flesh, and is in first-rate condition.

In connection with the report of this case I will pass a photograph taken from another case where the disease was allowed to run untreated until the whole thigh had become infiltrated with pus, and the patient lost his life in spite of the operation. The operation I performed was to lay open the knee with two long incisions (Figs. 3 and 4) which were united by a transverse cut so as to form an H-shaped incision, turn back the flaps and chisel out the bone. It ought to be said that in this case I did the best I could, the man refusing amputation.

The PRESIDENT: Will Dr. Shattuck speak of this case of osteo-myelitis of the shoulder?

DR. F. C. SHATTUCK: The first few days I supposed the case to be one of rheumatism. The history was suggestive of this disease, but my suspicions were awakened by the infiltration of the skin and muscles on the outer aspect of the shoulder joint, extending as far down as the lower attachment of the deltoid. In spite of this infiltration, I still regarded it as probably rheumatic, perhaps partly because I had just had a quite similar case in a man who presented no other evidence of suppuration whom Dr. Porter had seen with me, and who gradually but slowly improved under anti-rheumatic treatment.

In the boy, however, one spot soon softened and became fluctuant. I aspirated, drew pus, and then transferred the case to Dr. Warren.

The board-like infiltration of the skin and muscle,

with subsequent suppuration, differentiated the case sharply from the ordinary case of either rheumatism or gonorrheal synovitis.

DR. WARREN: In regard to the infection of the right knee and the left ankle, I attribute that to general sepsis, not to rheumatism, and yet such conditions simulate polyarticular rheumatism very closely indeed. A culture was made from the wound, and Dr. Wright reports that he found very numerous colonies of the staphylococcus pyogenes aureus, the most frequent organism found in osteomyelitis.

The PRESIDENT: I think what Dr. Warren said with regard to getting at these cases in the early stage is of great importance, and that a great deal of time for the patient is saved, and in hospital practice a great deal of time for the hospital itself is saved in getting the cases early. I don't think too much emphasis can be put upon this.

DR. WARREN: In the next bed was a man who had had acute osteomyelitis, and had had his first opera-

FIG. 3.

FIG. 4.

tion for the removal of the sequestrum five years after, and was just having his second operation for the attempt to heal the old sinus about ten years after the first.

DR. HARRINGTON: I don't see how in the early stages you are going to make the diagnosis much earlier than it was made here. I wonder if Dr. Shattuck thinks now if he had a similar case he would know earlier.

DR. SHATTUCK: Not more than a week or so earlier. It was about three weeks before it came to operation. I don't see how you could get hold of it much quicker than that.

DR. WARREN: Of importance in the diagnosis would be the age of the patient; it comes on at this period of life. Also the locality of the disease — either the head of the humerus, the lower end of the femur, or the upper end of the tibia being favorite seats; then, too, very intense pain, perhaps chill. The age of the patient, I think, ought to put us on the alert. Primary attacks come between puberty and twenty-five years of age; secondary attacks, which are not uncommon, may be recognized easily by the old scars.

A CASE OF OSTEO-SARCOMA OF BOTH SUPERIOR MAXILLÆ.

DR. J. C. WARREN: The tumor, of which the following is a photograph (Fig. 5), was of seven years' duration and was sent into the hospital by Dr. Cabot. It was a very slow-growing tumor, and I operated upon it by the usual method of cutting down, turning back the cheek and performing the regular operation for resection of the upper jaw. When I got the left upper jaw out, I found a good deal of the disease remained, and removed the right upper jaw also. The tumor is, as you see, a large one. All that was left

FIG. 5.

inside the mouth was the soft palate, and a rim of mucous membrane on each cheek. These were stitched together, and the corners tightened until the hole which separated the mouth from the nasal fossa was diminished one-third in size, and that diminished still more by cicatrization. The patient has been fitted with a plate, and you can see how little deformity there is in a man both of whose upper jaws are gone. He has only just had his plate fitted, and does not speak very plainly. The point of the case is to see how little deformity there is. The operation was performed about two months ago, November 28th.

The patient was then shown with the plate removed.

ASEPTIC INCISION WITH A SIMPLE FRACTURE.

DR. J. C. WARREN: Now that we have means of taking cultures and knowing where we stand, whether we have a septic or aseptic wound to deal with, we can make ventures we did not dare to do before. It is to illustrate this point that I report the following case. The patient was caught between the couplings of a freight car and an engine January 23, 1897. He was brought to the hospital; and the next morning the

whole leg, from the toes to the knee, was intensely swollen and black-and-blue—the skin shiny, glistening and pale. He was suffering a tremendous amount of pain. I asked Dr. Richardson and Dr. Porter to see him in consultation, and they both decided that it was important to lay the integuments open freely. I had hesitated to do that, as it was a case of fracture and I felt in doing that I was going to make a compound fracture; and we know how hard it is to make compound fractures in the neighborhood of the ankle-joint heal with antiseptic treatment. But it was a question of saving the leg. He was etherized, and an incision made from the upper malleolus nearly to the head of the tibia, down through the skin. This did not relieve the tension entirely, and an incision was made through the deep fascia. Then the muscle bulged up of a deep claret color, so that it was almost a question whether it was muscle or blood-clot so dark was the color. There was no hemorrhage except from two small arteries. A similar incision was made over the outer malleolus. Through the outer incision the interior of the joint could be seen. Through the inner incision the broken malleolus could be felt, showing it to be Pott's fracture, with laceration of the joint. The incision was aseptic; it was dressed with a dry aseptic dressing, and the moment the patient came out of ether his pain had gone. Looking at the wound forty-eight hours afterwards, it occurred to me that a culture should be taken from the wound; and if it was found to be sterile, these large wounds should be sewed up again. The report came that the culture was sterile, and consequently sutures were put in and the greater part of the long incisions were sutured; and I produce the man to show how we have practically changed a simple fracture into a compound for the purpose of saving the limb and the compound fracture back again into a simple one, or nearly so, after the danger had passed. It shows what the laboratory enables us to do.

The PRESIDENT: I should like to say a word in addition to what Dr. Warren has said. It seems to me the incisions which he made saved a large amount of gangrene of the skin which would otherwise have come about, and it was with that in mind that I advised the incision. I think it would ultimately have resulted in amputation of the leg, so much of the skin would have sloughed if it had not been incised; and I would like to report briefly in connection with this an operation I did some months ago, in which I converted a simple fracture into a compound fracture for the purpose of getting a better position. A lady in riding a bicycle sustained a fracture of both bones of the leg, and the fracture of the tibia was so oblique that it was impossible to keep the fragments from sliding by. A radiograph was taken. I told her there would be a deformity. I also told her of the slight danger there would be in making it a compound fracture, and she consented at once. The operation was done successfully. It was made a compound fracture, and wired, and immediately closed up; and she is now out of the hospital wearing a plaster, so that we have not had a second picture taken.

A CASE OF EXTRA-UTERINE PREGNANCY.

DR. J. C. WARREN: The patient, a young unmarried woman, had her catamenia the last time October 25, 1896. No flowing in November. In December, about the time when the catamenia should have ap-

peared, she had a sharp pain, and a slight flow from the uterus followed. That was December 27th, the time apparently the rupture took place. She entered the hospital the next day; and the operation was performed on December 29th, and the tube in question removed. On December 30th she passed the decidua. The patient made an excellent recovery, although in an extreme condition at the time of the operation. Here is the tube, and here are drawings of the decidua; and it is clear that the flow which came from the uterus was the flow from this membrane.

A CASE OF PYLORIC STRICTURE.

DR. W. W. GANNETT: The case is one of pyloric stricture, with dilatation of the stomach, hypertrophy of its wall and secondary catarrhal gastritis. The medical interest of the case relates to the differential diagnosis of the pyloric stricture.

The patient is forty-nine years old, of good family history and good past history.

Previous to six years ago he abused alcohol, and has always used tobacco to excess.

Four years ago slight gastric indigestion came on, giving but little trouble at first, but gradually increasing till two years ago, when vomiting became a prominent symptom, but which act gave immediate relief to the distress in the stomach, so much so that he frequently induced it by the finger in the throat. Nothing especial was noticed by patient as to the vomitus except the recognition at times of food eaten several days before. The amount of vomitus he states to have been occasionally two quarts. Eructation of gas has been nearly constant.

A loss of weight of twenty pounds occurred in two years. In June last he gave up work on account of weakness. For six to eight months previous to the entrance to the hospital he had noticed marked peristaltic movements in the stomach. Thirst, hunger and constipation have been marked. Stools did not attract his attention.

Patient entered the hospital September 16, 1896. A well-developed, fairly-nourished man. A harsh, dry skin, slightly coated tongue. Pupils equal, react to light, normal patella reflexes.

Heart, lungs and urine negative. No cachexia. Epigastrium prominent. Marked peristalsis of stomach. Succussion marked.

The usual investigation of the stomach showed its capacity to be 2,300 c.c.; and when distended with air, it reached well into the hypogastrium. The contents were undigested, fermenting food. Peristalsis active at all times; was marked after washing.

The evidence thus far offered proves sufficiently the existence of the dilatation of the cavity and hypertrophy of the wall of the stomach. Inasmuch as these result practically always from obstruction at the pyloric orifice, the rest of the evidence offered will relate to the data to be obtained for differential diagnosis of stricture.

During the three weeks stay on the medical side the stomach was washed out nearly every day. Examination of contents showed absence of HCl three times — 17th and 21st of September and 4th of October; presence of free HCl twice — September 28th and October 3d. Lactic acid present in all specimens. Examination of the blood showed 4,984,000 red corpuscles and 4,800 white, and 70 per cent. hemoglobin. Leucocyte count before meal 4,800; four hours

after meal 7,200, showing distinct digestion leucocytosis. No permanent leucocytosis.

Repeated examination by palpation in various portions of patient and varying degrees of distention of stomach failed to show evidence of tumor about the stomach or its neighborhood. Neither could a movable kidney be found nor any mass which by pressure from without or by retraction might cause obstruction.

Under lavage and regulated diet some improvement in the condition took place.

Weighing the evidence obtained by three weeks' study of the case, the preponderance was in favor of stenosis of non-cancerous origin. These points were the following: the duration of the disease; absence of cachexia; absence of secondary anemia; presence of digestion leucocytosis and absence of persistent leucocytosis; presence of free hydrochloric acid on two occasions, especially at a time when the catarrhal condition had been benefited by the lavage; absence of tumor by palpation. While all these factors were points against cancer, there has been no characteristic symptoms of peptic ulcer. But bearing in mind the frequent existence of scars at the autopsy, where no symptoms of ulcer have occurred during life, less stress need be laid on the absence of such positive evidence.

The evidence collected in three weeks so strongly pointed to stricture of benign origin that operation was advised.

Dr. Beach kindly saw the case with reference to exploratory laparotomy, and with his approval, as well as the consent and approval of the patient, it was done.

PYLORAPLASTY.

DR. H. H. A. BEACH: In describing the surgical side of the case presented by Dr. Gannett, I wish to testify to the judicious preparatory treatment the patient had received while in his hands, which, by reducing the distention and improving his general condition, facilitated the operation and materially added to his chances of recovery.

The stomach, somewhat enlarged, was carefully explored through an abdominal incision of five inches in the median line. At the pyloric end there was firm thickening but no adherence to the neighboring parts. A straight incision of an inch was made into the stomach, just above the stricture. By passing the finger in that direction the usual valve-like opening was found nearly closed by the contraction of a firm fibrous ring as thick as the little finger. The incision was continued in the long axis of the pyloric end of the stomach through the stricture and into the duodenum for an inch. The stomach was found empty, having been washed out immediately before etherization. There were no enlarged glands nor any condition that suggested malignancy. The stricture material was dense and tendinous-like in structure, and no objection appeared to the use of it in making a new pylorus and closing the wound.

The extreme ends of the incision were brought together by sutures which changed its direction to a line crossing it at a right angle. The lumen of the pylorus had been increased so as to admit three fingers. A double row of eighteen Lembert fine silk sutures were used to complete the union of stomach and duodenum. Two small gauze wicks were left from the pylorus to

the abdominal wound which was then closed as usual with the exception of two provisional sutures, to permit the withdrawal of the wicks (Figs. 6 and 7). This operation first employed by Henieke and Mikulicz independently of each other, not only removes the stricture but creates a new pylorus.

His recovery and convalescence were uneventful. The temperature on one occasion reached 99°, and once later, after a transfer to another ward, 100°. His pulse rose once to 104. During the remainder of the time it ranged between 60 and 90. His nutrition

FIGS. 6 and 7.

was provided for by enemata for the first two weeks and supplemented after the fifth day with small quantities of diluted peptonized milk by the stomach, gradually increased until sufficient was taken to make the enemata unnecessary. After that the diet was gradually increased by broths, oysters and eggs until three weeks after the operation, when he was eating chicken and chops and gaining rapidly. Five weeks after the operation he was walking about, and weighed 111 pounds, a gain of 15 pounds. In three weeks more he weighed 123½ pounds. For the first month after leaving his bed he was troubled with more or less distention and some eructations in the latter part of the day. These were relieved by an occasional washing out of the stomach, and restricting his diet. His appetite was ravenous, and his general gain remarkable.

On December 7th the gastric contents contained free HCl. and a small amount of free lactic acid.

Report on January 18, 1897. Feeling well. Has no distention of stomach or sour eructation. Takes no medicine. Is earning his living, and weighs 132 pounds, a gain of 36 pounds since the operation, October 7, 1896.

February 10th. Patient exhibited. Weight 135 pounds. Has no distention or sour eructations. Is at work and eating anything he desires.

DR. E. G. CUTLER: I should like to say that the diagnosis was a very careful and logical one, and the operation eminently successful. The result is very striking in every way, and reflects much credit on both Dr. Gannett and Dr. Beach.

The PRESIDENT: It seems as though when a brilliant result has been reached there is nothing to be said on such a case. It is certainly extremely interesting to have heard the account both medical and surgical of the case.

NEPHRITIS, MOLLUSCUM CONTAGIOSUM: DEMONSTRATION OF MICROSCOPICAL PREPARATIONS OF THESE TWO DISEASES.

DR. J. H. WRIGHT: The case of nephritis was one characterized by extensive general edema, which had been treated in Dr. Shattuck's wards for some months.

The lesions in the kidney consisted in extensive, obliterating, degenerative changes in the glomeruli, an increase in the interstitial tissue and various degenerations of the secreting tubules. The condition was essentially that of a chronic glomerule nephritis.

The specimen from molluscum contagiosum was shown for the reason that it exhibited very clearly the so-called parasitic bodies in the cells of the tumor. That these bodies are more probably the products of cell-degeneration seemed clear from the examinations of the specimen. The case was that of a child who had come under Dr. White's observation in the outpatient department.

SKIAGRAPHS OF COLLES' FRACTURE.

DR. WILLIAM M. CONANT: I wish to present to this meeting for their consideration a number of skiagraphs of Colles' fracture that have been taken at different stages of the accident — some before any reduction, some forty-eight hours after reduction has taken place, a few two or three weeks after, and two or three showing the final result at the end of four or five weeks.

The first set which I show is a normal wrist and then a plate which contains a Colles' fracture on one side and a sprain of the wrist on the other. One point that I wish to bring out is that in almost every case shown there is a fracture of the styloid process of the ulna as well as a fracture of some part of the radius.

Another point that will be understood in looking over the skiagraphs is that there appear to be three types. The first one is that of the boy, in which there is a fracture through both the epiphyses and also a fracture of the styloid of the radius. The deformity in such cases is very similar to the deformity in a Colles' and might be mistaken for a true Colles'.

The second type is shown by the skiagraph that demonstrated a chipping off of the outer edge of the radius taking in the styloid of the radius; and the other form is an oblique form, which runs from the outer to the ulnar side, and usually goes into the joint running across the whole lower extremity.

One of the skiagraphs shows a fracture of the wrist

as it entered the out-patient department before anything was done. One is much disappointed that it shows no greater amount of deformity, because it was very marked in the fracture as a whole. There are several skiagraphs which show the result taken soon after the fracture was set, and enable one to tell whether or not the process was good. Another set was taken two weeks after the accident, and shows the beginning of the callus, with a certain amount of blurring of the lines of the bone. The last set were taken, one at three weeks, one at four, and another at five weeks. All of these are instructive as showing that there is comparatively little deformity in the plate itself; and careful notes of the cases show that there is almost no deformity as far as the different motions of the wrist is concerned.

As most of these cases were put up first by the seniors in the accident-room, it seems to me that they demonstrate with what care fractures of this sort are treated by the house-officers.

The things especially noticeable in this set of plates, and in the history of the patients as seen from time to time, is that it has given us definite data to work upon, and has allowed for the correction of any deformity which may have existed before it was too late to mould the bones. It has also demonstrated that, in addition to the fracture of the lower end of the radius, there is almost always a fracture of the styloid of the ulna. I am, however, somewhat surprised that in some of the plates there should be so much apparent deformity when none could be felt or demonstrated by touch. I am therefore led to believe that the skiagraph somewhat exaggerates the amount of injury received, and must therefore be taken as showing an interesting condition as far as the union of the bones is concerned, but should not be used as a means to exaggerate in the eyes of the patient the injury from which he is suffering. It has been my custom in taking these skiagraphs not to let the patients see them, lest the inference which they should draw from the deformity be magnified out of all proportion, from their lack of exact knowledge of just what the deformity means.

DR. W. A. BROOKS, JR.: I should like to show these radiographs. Two of them are of the same fracture, and were taken shortly after the accident happened. They show clearly, what was known before the use of the x-rays, namely, that the deformity on the back of the wrist is largely due to the prominence of the lower end of the upper fragment, of the radius, while that on the anterior side is due to the displacement of the lower fragment. The study of this fracture, by means of the x-rays, has deeply impressed me with the importance of not using too much violence in reducing the impaction. The fragments should be *moulded* into their proper positions, after the impaction has been broken up as gently as possible. With the hand half-way between pronation and supination, the lower fragment is forced in this manner away from the upper, and then moulded towards the ulna, into its normal position. Care must be taken that the lower fragment is not pushed too far toward the ulna, as is shown by this radiograph. If it is, however, it can be corrected by the use of properly applied pads, as I am able to show by this radiograph, which is of the same fracture as the last, but a week later, and after Dr. Mosier, the house-officer, had applied pads with the object of separating the two bones.

DR. BEACH: After a considerable use of the x-ray and admitting the enormous advantage it gives surgery in many directions, it seems to me that there is another side to the question. When a surgeon assumes the charge of an injured limb he accepts a contract to use reasonable care toward the restoration of its integrity. He is not bound to extraordinary care or measures. In changing the standard by which the quality of the surgeon's work shall be measured and estimated, from what has been accepted heretofore, to the ideal suggested by x-ray applications, is to require such extraordinary service of the surgeon, as to demand exceptional precautions for his own protection. The useful limb and symmetrical contour no longer satisfy the individual who demands a restoration of the anatomic outline of the fractured bone, however well the uniting callus may have strengthened and united the splintered fragments. Where such a result is expected, it is just after a proper representation of the fact, for the surgeon to require the opportunity of *seeing* the relation of the fractured ends through an incision and adjusting them carefully — retaining their apposition by wire if necessary, in place of attempting the adjustment through varying degrees of fat and skin, with the added risk of displacement beneath the splints — the patient accepting the additional risk from the conversion of a simple into a compound fracture.

The appearance of bony union shown by the x-ray may give a totally inadequate idea of the solidity and utility of the junction to one not accustomed to x-ray pictures; for instance, the photograph by the ray of a normal knee-joint shows a considerable space between the condyles of the femur and the head of the tibia. If these were fractured ends, they would be reckoned by the uneducated observer as imperfectly united, the cartilages actually filling the space appearing as mistily defined as the soft tissues.

DR. C. L. SCUDDER: Apropos of what Dr. Beach has just said, I have been extremely interested in fractures of both bones of the forearm occurring in children. The space between the bones at the centre of the shaft being greater than the space at either end, one finds that usefulness in pronation and supination is greatest when the fracture occurs at the middle of the shaft. In a case the other day a radiograph was taken in which the fracture was near the epiphysis. On the surface the alignment was perfect, but the radius had approximated to the ulna so that there was one-half to three-fourths inch separation of the fragments and yet motion and usefulness were perfect; certainly no judgment should be brought in court in such a case against the surgeon because of evidence produced through the use of the x-ray — the radiograph showing considerable deformity.

I have been very much interested in these radiographs in connection with Colles' fracture and have been making some in the out-patient department. The thing I have discovered is that in adults, where there is not the opportunity for a separation of the epiphyses of the ulna, there is a tearing of the cartilage off of the lower end of the ulna without any fracture of the styloid process; in children there is a separation of the epiphyses of the ulna in Colles' fracture; in adults there is found a lesion of the cartilage from off the surface of the ulna, as was described by Moore, of Rochester, some years ago. It is important to recognize a lesion of the ulna in Colles'

fracture in addition to the lesion of the radius to which attention has invariably been directed. It is important also not to manipulate the wrist by grasping the hand in the old way and making tremendous adduction to break up the impacted fragments of the radius, but to manipulate each fragment by taking hold of the distal and proximal fragments with the fingers and to replace carefully and thus not add to the bone lesion a sprain of the wrist which it seems to me in old times was done.

A CASE OF SPLENIC MYELOGENOUS LEUKEMIA.

DR. H. F. VICKERY: The patient I have to show is of Russian birth, forty-five years old, who has had a winter cough for four or five years, but who assures me that he feels as well as twenty-five years ago. About two years ago he had an attack of diarrhea, and since that time he has occasionally had some looseness of the bowels. In 1872 he had apparently articular rheumatism, and there is now a mitral regurgitation which does not concern us at present. There is a history of malaria in childhood, and he also once had an ulcer on the lip which was cankerized, and which was thought, as near as I can understand what he said about it, to be a chancre, but no evidence of syphilis since that time can be obtained. He has been reduced in the last twenty-five months from 228 pounds down to 177 pounds, and perhaps rather to his advantage. The striking things about him are that, with a very large spleen indeed and a disease of great gravity, he should feel so very well. The blood-count of the red corpuscles is very nearly normal, being 4,016,000 corpuscles to the cubic millimetre. The white cells number 546,000. They have been counted repeatedly by several persons, and all substantially agree. A differential count of the white corpuscles has been made repeatedly. Dr. R. C. Cabot, at my request, made the blood-count, and reported 28 per cent. of myelocytes in a count of 700 white cells; that is, this man has the so-called splenic myelogenous leukemia, in spite of which he feels perfectly well. He is here, and perhaps an examination of the spleen would be of some interest. He has occasionally a little nose-bleed, and has had lately swelling of the ankles, but not more edema than could be accounted for by the mitral regurgitation. Dr. Greenough has prepared a stained specimen of the blood, which is under the microscope. The large proportion of myelocytes is very striking.

In conclusion, I desire to express my thanks to Dr. Fitz for taking this patient into his wards in order that he might be shown to-night.

THE PHONENDOSCOPE.

MR. W. H. SMITH, Medical House-Officer: To demonstrate the practical value of the phonendoscope, for which so much was claimed by Professor Bianchi, of Florence, a series of over 150 cases has been examined. The observations extend over a period of several months, during the service of Dr. Fitz and Dr. Gannett at the Massachusetts General Hospital. Each case has been first examined with the stethoscope and then with the phonendoscope. The following conclusions have been reached:

In work upon the lungs, the phonendoscope has been found of little value. Owing to the way sounds are magnified, the noise of the inspiratory and expiratory murmurs tends to obscure other signs. In ten

cases, fine, moist râles were overlooked entirely by this instrument. Even with the removable disc in place, which in most examinations should be removed, such an increase in the sounds is heard as to limit its value in the analysis of inspiratory and expiratory murmurs.

For ascertaining the size of the liver, spleen and stomach, the facility and accuracy with which these organs can be mapped out with the phonendoscope with gentle percussion, would seem to recommend it. Stomach tympany is easily differentiated from that of colon by this means.

For the mapping out of the kidney area we have not found the instrument of much assistance.

It is in the examination of the heart, however, that it has been found of especial value. (1) It makes more absolute the diagnosis of myocarditis with dilatation, where the chest walls are thick, and percussion of the cardiac area necessarily difficult. By means of the phonendoscope, the difficulties are much less. Furthermore, murmurs in several instances were discovered with this instrument, which could not be heard with the ordinary stethoscope. In one case, of carcinoma of the stomach, with myocarditis, a soft systolic murmur at the apex was entirely overlooked with the phonendoscope, but easily heard with the stethoscope. A possible explanation for this lies in the fact that owing to the extreme degree of emaciation present in this case, the larger cap of the phonendoscope was less accurately apposed to the chest wall, than was the smaller bell of the stethoscope. With the staff in place on the phonendoscope the murmurs were readily audible.

In one case a pericardial friction rub was first discovered by means of the phonendoscope; several observers failing to find it with the ordinary stethoscope. The objection was raised that the sound was extraneous; yet its presence during a period of two days, associated with sharp precordial pain, in a girl suffering from rheumatic polyarthritis; its absence in 20 or 30 subsequent observations upon the same case; and the fact that the sound was never present in any of the other cases examined, seem to negative the objection.

The fetal heart can be heard much more readily with this instrument than with the ordinary stethoscope. It does not replace the stethoscope, but serves as a necessary adjunct to its use.

A PHYSICIAN DIES UNDER CHLOROFORM.—Dr. James A. Ethridge, a well-known physician of Macon, Ga., died March 14th from the effects of chloroform. Dr. Ethridge was about to undergo an operation for fistula, and almost at the first inhalation of the chloroform his pulse and respiration ceased, and every effort to resuscitate him failed. Upon a preliminary examination of Dr. Ethridge no contraindication to the use of chloroform could be discovered by the physicians in attendance. Dr. Ethridge was about forty years of age, and had practised his profession successfully in Macon for many years. He was a member of the Board of Health of Macon, visiting physician to the city hospital, and surgeon to the Georgia Southern and Florida Railroad. — *Atlanta Medical and Surgical Journal*.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, APRIL 15, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS.

THE DUTY ON BOOKS IN THE DINGLEY BILL.

It was one of the good features of the McKinley tariff bill that it put on the free list books and works of art. The framers of that bill, while aiming in the main at protective rates, intended largely to exclude foreign products from the markets of this country, but they still recognized the fact that untrammelled freedom of exchange in art, in literature and science is a good thing, and that a tariff on knowledge is an abomination. It is true that an exception was made in reference to books published in England, which, unless transported unstitched, were still kept on the dutiable list in response (doubtless) to the demands of American publishers — and this objectionable feature was allowed to remain in the Wilson bill; but both the McKinley and the Wilson bills admitted without duty books published in foreign languages.

We need not dwell on the advantages to public libraries — and we emphasize medical and scientific libraries — of the introduction of all foreign books free of duty, these advantages being obvious to every one who thinks of the limited funds at the disposal of such institutions and the fact that every dollar paid for duties curtails by so much the amount available for literature.

The question in its relation to education presents itself thus: Immense sums are annually collected by government from citizens for schools and other institutions for learning, that is, to furnish the means of knowledge. School-books are supplied 'gratis' to schools and to pupils. Works of science and literature are among the means to a liberal education, and it should be made easy for citizens to obtain them, rather than difficult by a burdensome tariff. In other words, a tax on knowledge is monstrously incongruous with a governmental policy which aims to encourage, enforce and foster education. The general principle of "protection" may be right or it may be wrong — we are not here concerned with this question — but none of the considerations applicable to the fruit-raisers in

California or Florida, the wool-growers of Ohio, the lumber merchants of Maine, are applicable to the products of art, literature or science; and it is worthy of note that no artist of prominence, author or publisher appears among the petitioners asking for the imposition of a duty on these productions. As has been well observed, our American artists do not need to be protected, they produce many of their best works in studios in Paris, Rome, and on the banks of the Arno, side by side and in fair competition with their foreign brothers. Genius of that order will thrive better under competition than under protection.¹ With regard to the imposition of a duty on books now admitted free, we have the testimony of Mr. Edwin Ginn, one of the largest manufacturers of school, college and educational books in this country, "that it would be a great misfortune to the educational world, and no publisher with any breadth of character and any interest in the good of his country could wish to make any money on such publications as are in this (Dingley) law compelled to pay duty."

With regard to works of science and of medicine, with which readers of this journal have the most interest, it may be said that few of our legislators realize the injury which will be done to physicians by reimposing a tax on foreign books. As has often been said, genius is cosmopolitan; there is but one Virchow, one Charcot, and their published works belong to the whole world. No familiarity with the writings of the late Mr. Blaine or with American histories, or even with the speeches of Nelson Dingley, Jr., or of our present chief executive, though well bound in protected muslin or vellum and translated into classic German, will to the intelligent physician, anxious to be abreast of the times, compensate for the failure to be acquainted with Leube, Lancereaux, Wundt, Meynert, Koehler, Vulpian, Chantemesse, and other original workers in various departments of medicine or surgery whose writings are to but a very small extent published in this country and available in translation. It is an undoubted fact that during the six years in which foreign medical works have been admitted free there has been a considerable addition of such works to the libraries of physicians throughout the country. Doubtless the number of physicians who habitually purchase books in languages other than English is relatively small, but these few are generally men of moderate means who ought not to be taxed because they desire to know Italian, French or German and study the masterpieces of medical literature in the language in which they were written. It may seem incomprehensible to the Ways and Means Committee, but it is an actual fact that the adding of a few dimes or dollars more to the price of a book in the way of a tax will very often operate as a deterrent from purchasing, and so no revenue is obtained from this source. Many physicians will think twice before they will decide whether they can afford the "Nouveau Traité de Médecine," and they will be apt to forego

¹ Speech of Hon. Saml. W. McCall, in the House of Representatives, March 29, 1897.

the purchase if a duty of twenty-five per cent. is added. Besides there is the delay and vexation consequent on customs — entries and appraisals with additional tributes to official red tape, or if the book comes through the post-office, delay and cost consequent on inspection by the government officer whose valuation is often wide of the mark, but whether high or low must be accepted without protest. It cannot be maintained that the little revenue which the United States government is likely to obtain from this source offsets all the inconvenience and loss to individuals.

There are occasions when considerations of gain or of revenue should give way to measures intended to promote the intellectual and moral good of the community at large, and this tax on the means of learning — called by the *New York Tribune* a "tariff on ideas," and appropriately stigmatized as "barbarous" and "medieval," should be emphatically repudiated by the Senate as a step backward. We are pleased to note that in the House, prior to the final vote on the bill, some concessions were made to public libraries and institutions of learning which are to be allowed to continue the importation, under certain restrictions, of the products of art, science and literature. The earnest plea made by Representative McCall, and ably seconded by other representatives from Massachusetts (notably Mr. Moody), for the adoption of a still more liberal measure was without effect. It is to be hoped that the Senate, which now has the tariff bill in hand, will insist on keeping books on the free list, although Mr. Dingley declares that "we publish an abundance of foreign books in this country."

THE BACTERIOLOGY OF EPIDEMIC CEREBRO-SPINAL MENINGITIS.

In view of the present epidemic of cerebro-spinal meningitis in Boston, it may be of interest to summarize what is known in regard to the etiology of the disease. Meningitis may be caused by a variety of organisms of which the most common are the tubercle bacillus, the staphylococcus pyogenes aureus, the streptococcus pyogenes and the micrococcus lanceolatus (pneumococcus of Fraenkel and Weichselbaum). The organism usually found in sporadic and endemic cases of acute cerebro-spinal meningitis has been the micrococcus lanceolatus, and it has been generally assumed that the epidemic form of the disease has been due to the same organism.

In 1887 Weichselbaum reported finding in the exudate of six cases of cerebro-spinal meningitis an organism which he named the diplococcus intracellularis meningitidis, on account of its morphology, and its situation usually within the leucocytes of the exudation. Little attention had been paid to his discovery until an article by Jaeger appeared in the *Zeitschrift für Hygiene* in 1895. Jaeger investigated bacteriologically ten cases of cerebro-spinal meningitis which appeared in epidemic form among the soldiers in bar-

racks and in all of them found the diplococcus intracellularis meningitidis.

The organism has the following peculiarities. It closely resembles the gonococcus, appearing in the form of a diplococcus of which the two halves are broader than they are long, and flattened along the line of apposition so that they appear separated by a perfectly straight line. Many appear as tetrads, and the chains found in the water of condensation of cultures show a longitudinal line due to the transverse division of the diplococci into tetrads. In the meningeal exudation the organisms are found almost wholly within leucocytes, either singly or in large numbers. In the latter case a cover-slip preparation closely resembles the picture presented by gonorrheal pus. Jaeger claimed that he could often detect a faint capsule around the organism, but this observation lacks confirmation. The diplococcus intracellularis stains readily with the ordinary bacterial stains, such as Löffler's methylene-blue solution. It is decolorized by the Gram method of staining, as was first pointed out by Weichselbaum. Jaeger maintains that although the organism is readily decolorized in sections by Gram's method, it is not decolorized in cover-slip preparations. This observation on his part is unquestionably wrong, due to too short washing out in alcohol, for the diplococcus intracellularis decolorizes as quickly as the gonococcus. Both require longer washing in alcohol than the typhoid or colon bacillus. The method sometimes employed for differentiating gonococci (Gram's method followed by vesuvium), gives very good pictures with the diplococcus intracellularis. The organism grows readily on the ordinary opaque Löffler's blood-serum mixture used for diphtheria bacilli. In twenty-four hours the colonies reach a size obtainable on glycerine agar (recommended by Jaeger) only after forty-eight hours. The colonies are slightly elevated, round, viscid, fairly transparent and about one millimetre in diameter. Inoculations into animals are successful only when made into the pleural or peritoneal cavity.

The differential characteristics of the micrococcus intracellularis meningitidis may be briefly summed up as follows: It resembles the gonococcus morphologically, in its situation usually within pus cells, and in its reaction to Gram's method of staining, but differs from it in growing on ordinary culture media, and in being virulent for animals when properly inoculated. It differs from the micrococcus lanceolatus in form, in the lack of a capsule (at least of a well-marked capsule), in its reaction to Gram's method of staining, and in the fact that it is not virulent for animals when inoculated subcutaneously but only when injected into the pleural or peritoneal cavity.

Much interest is being taken in the various pathological laboratories in Boston, in the investigation of the cases afforded by the present epidemic. The fluid obtained by lumbar puncture has proved of the greatest value both clinically in clearing up doubtful diagnoses, and bacteriologically in furnishing the means of determining to what organism the lesions are due, for

by the time the cases come to autopsy the organisms have often almost or entirely disappeared so that cover-slip preparations and cultures prepared from autopsy material have given mainly negative results. When lumbar punctures are made early the organism is usually found in large numbers in the pus cells and cultures yield an abundant growth.

It is too early yet to report the results obtained at the different hospitals, but in nearly every case examined bacteriologically the diplococcus intracellularis meningitidis of Weichselbaum has been found. One case only was clearly due to the micrococcus laeolatus. The fluid obtained by lumbar puncture has varied from a very slightly cloudy serum to thick pus. The exudation found in the meninges at autopsy has likewise varied from a slight amount to a thick yellow layer. The exudation in the meshes of the pia is singularly rich in fibrin and very tough, so that cover-slip preparations and cultures are made from it with some difficulty. The organism to which the lesion in a given case is due cannot of course be determined except by careful histological and bacteriological examination. The value of such knowledge, is, however, self-evident, if the fact claimed by Jaeger is true that in at least a certain number of cases the organism is found in the nasal secretion of those affected with cerebro-spinal meningitis.

The few facts above presented in regard to the character of the cases of cerebro-spinal meningitis now prevalent in the city would seem to show that certain epidemics, at least, are not due to the micrococcus laeolatus but to the diplococcus intracellularis meningitidis.

MEDICAL NOTES.

THE MEDICAL SCHOOL OF THE UNIVERSITY OF ILLINOIS.—The College of Physicians and Surgeons, of Chicago, has recently become the Medical School of the University of Illinois.

THE NINTH INTERNATIONAL CONGRESS OF HYGIENE AND DEMOGRAPHY.—This congress, which was to be held at Madrid next autumn, will probably be postponed till Easter, 1898, or given up entirely. The reason for this action is stated to be the distress which prevails in Spain owing to the various wars in which she is engaged.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, April 14, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 79, scarlet fever 73, measles 132, typhoid fever 5.

THE BOYLSTON PRIZE.—The Boylston Medical Prize of \$150, for 1897, has been awarded to J. Francis Walsh, M.D., for an essay entitled, "The Anatomy and Functions of the Muscles of the Hand and of the Extensor Tendons of the Thumb."

APPOINTMENTS AND RESIGNATIONS.—Drs. Augustus Thorndike, E. H. Nichols, John Dane and J. S. Stone have been elected junior assistant-surgeons of The Children's Hospital; Dr. John T. Bowen, dermatologist; and Dr. George L. Goodale, assistant-surgeon in the Throat Department.

Dr. George A. Harlow has been appointed district physician to the Boston Dispensary, and Dr. Charles S. Wright, assistant-physician to the Department for Diseases of the Ear.

Dr. W. A. Dunn has resigned his position of trustee of the Boston City Hospital, after three years of service. Dr. C. H. Cogswell has resigned from the superintendency of the City Institutions on Long Island, and Dr. Lowell F. Wentworth, of Bridgewater, has been appointed to the position.

THE SURVIVAL OF ONE OF THE FITTEST.—At a recent meeting of the Clinical Society of the Boston City Hospital, a patient was presented who was convalescent from pneumonia. He is a sailor, eighty-four years old, and at various times in his life had been the victim of the following injuries: Fracture of the left femur (which had united with marked callus and two and one-half inches of shortening), of the left patella, of the head of the right tibia, of the left clavicle, of several of the lower ribs on both sides, of the index fingers of both hands (these presented marked deformity), of the left ankle, and of the right scapula. He had also suffered from double otitis media, bronchitis and asthma. He now has double incipient senile cataract. Several years ago he had had an epithelioma removed from the lower lip, and there had been no recurrence. The man's limbs are still muscular, though his age and the vicissitudes of his career have necessarily caused some wasting. His breadth of shoulders and depth of chest give evidence of what must have been extraordinary physical strength and endurance. He is never known to have suffered from pain in the back, sleeplessness, "that tired feeling," indigestion, loss of ambition, inability to do his work or concentrate his attention, restriction of the visual field, local anesthetic areas, or any of the other symptoms of traumatic neurasthenia or hysteria, so that he has not been deprived of his ability to earn his livelihood, or required provision for the care of his declining years by those who employed him at the time of his various injuries.

NEW YORK.

THE CONSOLIDATION OF TWO GREAT MEDICAL SCHOOLS.—A measure which has created much surprise in the profession, but which, it appears, has been in contemplation for some time, was made public on April 8th, when it was announced that the State Board of Regents at a meeting held in Albany on that date had effected the consolidation of two of the principal medical schools of New York City, namely, the Medical Department of the University of the City of New York and Bellevue Hospital Medical College. The name of the consolidated institution will be the New York University Bellevue Medical College,

and it is hoped to make it one of the largest and most thoroughly equipped medical schools in the world. It is stated that at the beginning it will have an annual income of about \$160,000, and the belief is expressed that this will from time to time be increased by gifts and legacies. The first formal step in the matter of the union was taken on March 17th, when the University corporation adopted a resolution inviting the faculty and trustees of Bellevue to join in the consolidation of their institution with theirs, upon a plan similar to that recently adopted when the University Medical College placed itself under the immediate care of the University. It is probable that the project of consolidation was hastened by the fire which two months ago partially destroyed the Bellevue building, which stands within the grounds of Bellevue Hospital, on city property, the lease of which expires in two years. Pending the refitting of the building the college was transferred to the Carnegie Laboratory, belonging to the Bellevue School, and, in anticipation of the expiration of the lease, a site for a new building was purchased. This adjoins the Carnegie Laboratory, and has a frontage of 75 feet on 26th Street and 150 feet on First Avenue. On this lot, it is announced, a handsome and commodious structure will be erected, and, in addition, the University Medical College building, which stands near-by, will be enlarged by the addition of two stories, making it eight stories in height. The manner in which the various professorships in the consolidated institution will be arranged from the faculties of the two schools has not yet been made public, and probably has not as yet been fully determined upon.

TO STAMP OUT SMALL-POX.—A special appropriation of \$37,500 has been promptly made by the Board of Estimate and Apportionment for the pay of medical inspectors engaged in the work of stamping out small-pox, although, happily, the present outbreak has by no means assumed alarming proportions. In making application for the appropriation President Wilson, of the Board of Health, stated that up to April 8th twelve cases of the disease had been reported. The most serious feature of the matter is that cases were found in eight different tenement houses.

A REMARKABLE CENTENARIAN.—Joseph Field, a farmer of Middletown, N. J., died recently at the advanced age of 104 years, six months, and six days, which is said to be well authenticated. He lived all his life on the farm where he died, with the exception of a short period spent in the produce business in New York. It is stated that he came of very long-lived stock, his father having attained the age of ninety-four and his grandfather, one hundred and two. He remained a bachelor up to his seventy-fifth year, when he married a young woman of twenty-eight, by whom he had three children. It is furthermore reported of him that he never used tobacco, but was "fond of good old home made apple-jack."

DEATH OF DR. CHARLES HAMMER.—Dr. Charles Hammer, a prominent physician of Schenectady, died at his residence in that city on April 7th, of apoplexy, at the age of sixty-five years. Dr. Hammer was largely identified with the New York State Medical Association and the American Medical Association.

Miscellany.

SIR WILLIAM MAC CORMAC AND QUEEN'S COLLEGE, BELFAST.

THE distinguished career of Sir William Mac Cormac, who was last year elected President of the Royal College of Surgeons of England, was recently commemorated by the presentation of his portrait to Queen's College, Belfast, of which he was alumnus. As he is the holder of the most distinguished position to which a British surgeon can aspire, a brief review of his life and work may not be amiss to our readers:

"He was born at Belfast, 1836, being the eldest son of Henry Mac Cormac, M.D., and Mary Newsom. He was educated in the Belfast Institution, in Dublin, and in Paris; he became Bachelor and Master of Arts, also Master in Surgery and Doctor of Science *honoris causa* of the Queen's University, and received its gold medal. He was afterwards a member of the Senate and examiner in surgery of the University. He was appointed surgeon, and afterwards consulting surgeon, to the Belfast Royal Hospital. He saw service at Metz and Sedan during the Franco-German war, 1870-1, as surgeon-in-chief of the Anglo-American ambulance, and during the Turco-Servian war, 1876. He has been senior surgeon and lecturer on surgery at St. Thomas's Hospital, and consulting surgeon to the French Hospital, Italian Hospital and Queen Charlotte's Hospital. He is a Fellow of the English and Irish Colleges of Surgeons, and has been examiner in surgery in the University of London. In 1881 he acted as honorary secretary-general of the International Medical Congress in London, and in consideration of his services in that capacity the Queen conferred upon him the honor of knighthood. He is a Knight of the Legion of Honor, Commander of the Orders of the Medjidieh, the Dannebrog, the Crown of Italy and the Takovo; also possessor of the Orders of the Crown of Prussia, North Star of Sweden, St. Iago of Portugal, Ritter Kreuz of Bavaria and Merit of Spain. Sir William Mac Cormac is the author of 'Work under the Red Cross' and treatises on 'Antiseptic Surgery' and 'Surgical Operations,' besides numerous surgical papers contributed to medical journals and addressed to medical societies."

Lord Dufferin presided at the ceremony of the presentation of the portrait, and in a speech full of his usual charm of words and manner, eulogized the personality and career of Sir William Mac Cormac, who responded in terms marked by loyalty to the college at which he received his medical education. The ceremony of presentation was as impressive as it must have been gratifying to the central figure and was attended by a large gathering of the alumni, as well as by professors and students of the college. The portrait was subscribed for by friends and former students of Queen's College resident in England, India and the Colonies.

Correspondence.

CHLOROFORM IN LABOR.

DENVER, COL., April 8, 1897.

MR. EDITOR:—In your issue of March 18th, the use of chloroform in labor is considered by Drs. Boland, Twombly and others. May one who has long been away from the city which gave us ether add a word to the discussion?

In four and a half years of medical study and hospital work in Boston, from 1878 to 1883, I never saw chloroform given, nor did I receive instruction as to its administration. I was taught that ether was the only anesthetic to use; and I admit freely that, as regards the very great majority of cases, I believe that teaching to have been correct, although probably one-half of the cases I have seen anesthetized in this State have taken chloroform.

For years, however, my firm conviction has been that chloroform should be preferred, in certain cases, as the safer and better agent, and my teaching has been in accordance with this view. Not to mention here some cases of albuminuria, bronchitis in aged people, and certain inflammatory conditions of the air-passages, we have, I believe, in labor a set of conditions demanding chloroform rather than ether.

One of the speakers stated in the discussion that ether "works just as fast, and gives us practically no anxiety at all." If the first proposition were correct, I should have nothing to say; but I am convinced, after an experience of several hundred cases in which I have used chloroform in labor, and previous to which I had for some years, used ether, that it is not so. Chloroform has, in labor, all the advantages attributed to it by Dr. Boland, and one more, of greater importance than any other excepting safety, namely, greater rapidity of action. It thus relieves the oncoming pain more quickly than ether. As the head distends the perineum the anesthesia may be pushed to the extent of surgical narcosis with great ease and rapidity, and without the excitement sometimes so troublesome with ether. I believe that no fair-minded physician, who will use the two drugs each in a dozen cases of labor, will use ether in labor thereafter excepting for operative cases, in which, at times, I use it myself.

Dr. Boland says of chloroform that, in childbirth, "it is practically as safe as ether." I believe this statement to be correct, all authorities supporting it so far as I know. I certainly have never seen a sign of danger, although the drug has been given often in my cases by untrained assistants.

If because, as one speaker stated, "we are born and bred up to it," we are to continue to use ether to the exclusion of all other agents, in spite of the teachings of scientific medicine; and if a great representative medical school is to utterly ignore in its teaching of practical anesthesia, as it did a dozen years ago, an anesthetic used by half the physicians of the world, I can only express the conviction that, in these matters, prejudice and conservatism have altogether too much weight. There can be no reason why, in selecting an anesthetic, the physician should not act exactly as in choosing a cathartic, using the one best suited for the particular case in hand. No medical community is justified in refusing to hear the other side of the question of ether or chloroform anesthesia.

In closing, I wish to add that, although we believe we are correct in considering ether to be the great anesthetic, we should not be so hide-bound as to refuse to give chloroform a fair trial in suitable cases. If the surgeons of the Massachusetts General Hospital, on the 16th of October, 1846, had wrapped themselves up in their conservatism, and refused to listen to "the other side of the story," the world would have waited for years for the glad tidings of anesthesia. Yours very truly, J. N. HALL, M.D.

A PRINCESS AS TRAINED NURSE.—Princess Frederick Leopold of Prussia is undergoing a regular course of training as a hospital and field nurse.

METEOROLOGICAL RECORD

For the week ending April 3d, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Amesbury	10,920	—	—	—	—	—	—	—

Deaths reported 3,523; under five years of age 1,087; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas and fever) 351, acute lung diseases 646, consumption 372, diphtheria and croup 133, diarrheal diseases 50, scarlet fever 41, typhoid fever 35, measles 31, whooping-cough 24, erysipelas 15, cerebro-spinal meningitis 13, small-pox (Chicago) 1.

From typhoid fever Chicago 7, New York, Philadelphia, Pittsburg and St. Louis 4 each, Boston and Lowell 2 each, Brooklyn, Cleveland, Washington, Charleston, Fall River, Lawrence, Springfield and Taunton 1 each. From measles New York 13, Chicago 8, Brooklyn 6, Philadelphia and Boston 2 each, Brockton 1. From whooping-cough Chicago, Philadelphia and Brooklyn 5 each, New York 4, St. Louis and Boston 2 each, Pittsburg 1. From erysipelas New York 6, Boston 3, Philadelphia 2,

Chicago, Baltimore, Pittsburgh and Worcester 1 each. From cerebro-spinal meningitis Boston 3, New York, St. Louis and Chelsea 2 each, Worcester, Lynn, Somerville and Brockton 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,992,524, for the week ending March 27th, the death-rate was 18.7. Deaths reported 3,939; acute diseases of the respiratory organs (London) 313, whooping-cough 98, measles 88, diphtheria 64, diarrhea 43, scarlet fever 30, fever 30.

The death-rates ranged from 12.9 in Croydon to 24.2 in Salford; Birmingham 19.9, Bradford 18.0, Brighton 13.7, Cardiff 15.6, Halifax 18.0, Leeds 16.7, Leicester 17.7, Liverpool 21.5, London 17.9, Manchester 24.0, Newcastle-on-Tyne 20.1, Nottingham 24.0, Oldham 21.5, Sheffield 18.7.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 3, 1897, TO APRIL 9, 1897.

Leave of absence for six months, to take effect on or about May 18, 1897, is granted CAPTAIN EDWARD R. MORRIS, assistant surgeon, Fort Spokane, Wash.

The leave of absence for seven days granted CAPTAIN HENRY S. T. HARRIS, assistant surgeon, is extended twenty-three days, Fort Preble, Me.

CAPTAIN EUGENE L. SWIFT, assistant surgeon, is relieved from duty at Fort Yates, N. D., to take effect upon the expiration of his present sick leave and ordered to Fort Slocum, N. Y., for duty.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 10, 1897.

C. U. GRAVATT, surgeon, when finished with examination for promotion April 5th, detached from the Museum of Hygiene, ordered home and then hold himself in readiness for sea.

J. A. GUTHRIE, passed assistant surgeon, detached from the "Katabdin," and ordered to the "Alliance."

J. F. LEYS, assistant surgeon, detached from the "Alliance," on relief and ordered to the "Vermont."

T. N. PENROSE, medical director, detached from the New York Hospital, June 5th, and placed on waiting orders.

G. W. WOODS, medical director, detached from the Mare Island Hospital, May 10th, and ordered to the New York Hospital, June 5th.

G. P. BRADLEY, medical inspector, ordered to the Mare Island Hospital, May 10th.

E. P. STONE, passed assistant surgeon, detached from the "Indiana," April 12th, and ordered to the "Bennington."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SIXTEEN DAYS ENDING MARCH 31, 1897.

CARTER, H. R., surgeon. Granted leave of absence for one day. March 27, 1897.

WHEELER, W. A., surgeon. Granted leave of absence for seven days from March 23, 1897.

BANKS, C. E., surgeon. Detailed as inspector of marine hospitals and marine hospital stations. March 9, 1897. Detailed to inspect stations of Cincinnati, O., Chicago, Ill., and Detroit, Mich. March 18, 1897.

BROOKS, S. D., passed assistant surgeon. To proceed from Port Townsend, Wash., to principal ports of Japan and China on special duty. March 30, 1897.

GEDDINGS, H. D., passed assistant surgeon. To proceed from Marseilles to Paris, France, on special duty. March 22, 1897.

STIMPSON, W. G., passed assistant surgeon. To assume charge of Marine Hospital, Port Townsend, Wash., in addition to quarantine station, during absence of Passed Assistant Surgeon S. D. Brooks. March 31, 1897.

NYDEGGER, J. A., passed assistant surgeon. Granted seven days' leave of absence from April 2, 1897. Relieved from duty in Hygienic Laboratory, April 24, and upon expiration of leave of absence to rejoin his station at South Atlantic Quarantine. March 29, 1897.

GARDNER, C. H., passed assistant surgeon. When relieved from duty at Chicago, Ill., on or about April 2, 1897, to proceed to Baltimore, Md., for duty. March 27, 1897.

SERAGUE, E. K., assistant surgeon. To proceed from Boston, Mass., to Washington, D. C., for temporary duty in Hygienic Laboratory. March 27, 1897.

PROCHAZKA, EMIL, assistant surgeon. To proceed from Reedy Island Quarantine to Delaware Breakwater Quarantine Station for temporary duty. March 29, 1897.

WICKES, H. W., assistant surgeon. To proceed from New Orleans, La., on or about April 3, 1897, to Boston, Mass., for duty. March 27, 1897.

GREENE, J. B., assistant surgeon. When relieved from duty at Baltimore, Md., on or about April 3, 1897, to proceed to Detroit, Mich., for duty. March 31, 1897.

CLARK, TALIAFERRO, assistant surgeon. To proceed to Chicago, Ill., for duty. March 27, 1897.

HASTINGS, HILL, assistant surgeon. To proceed to New Orleans, La., for duty. March 27, 1897.

LAVINDER, C. H., assistant surgeon. To proceed to New York, N. Y., for duty. March 27, 1897.

APPOINTMENTS.

TALIAFERRO CLARK, of District of Columbia; HILL HASTINGS, of Kentucky, and CLAUDE H. LAVINDER, of Virginia, commissioned as assistant surgeons. March 25, 1897.

TUFTS COLLEGE MEDICAL SCHOOL. EVENING LECTURES.

Hon. Hosea M. Knowlton, Attorney-General of Massachusetts, will deliver an address on "Medical Jurisprudence," Friday evening, April 23d, at 8 o'clock at the Chauncy Hall School Building, Boylston Street. The profession is cordially invited to be present.

CHARLES P. THAYER, *Secretary*.

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The annual meeting will be held at the Massachusetts Institute of Technology, Walker Building (corner of Boylston and Clarendon Streets), Room 22, on Saturday, April 24th, at 8 P. M.

The following papers will be read:

"Some Medical and Surgical Uses of the Röntgen Rays," with illustrations, by Dr. Francis H. Williams.

"Therapeutics of the Alimentary Canal," by Frauz Pfaff, M.D., Ph.D. Drs. A. L. Mason, E. G. Cutler, and G. Liebmann have been invited to participate in the discussion.

Business: Report of Librarian and Treasurer. Election of officers. Appointment of delegates to the annual meeting of the American Medical Association.

Supper at the Brunswick after the meeting.

JOHN G. BLAKE, M.D., *President*.

JOHN DANE, M.D., *Secretary*.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for Clinical Medicine, Pathology and Hygiene will meet at the Medical Library, 19 Boylston Place, Wednesday, April 21st, at 8 o'clock.

At 8-8.30. Short communications by Drs. J. E. Clark, E. C. Stowell and Henry Jackson.

At 8.30. Dr. J. L. Morse: "Infantile Atrophy."

E. W. TAYLOR, M.D., *Secretary*.

BOOKS AND PAMPHLETS RECEIVED.

On the Systematology of the Bacteria. Infantile Dysaeriosis. Can Tuberculosis be Diagnosed from the Blood? By C. Fisch, M.D., St. Louis, Mo. Reprints. 1896-97.

Transactions of the Eighteenth Annual Meeting of the American Laryngological Association held in Pittsburgh, Pa., May 14 to 16, 1896. New York: D. Appleton & Co. 1897.

Hypnotism in General Medicine; A Few Suggestions from Personal Experience. Symptoms of Speech Disturbances as Aids in Cerebral Localization. By J. I. Eskridge, M.D., Denver, Col. Reprints. 1897.

Introductory Clinical Lecture. Ulcers of the Cornea; Implantation of a Glass Ball for the Better Support of an Artificial Eye. Ophthalmia Neonatorum. By L. Webster Fox, M.D., Philadelphia, Pa. Reprints. 1896-97.

Nineteenth Annual Report of the State Board of Health of the State of Connecticut with the Registration Report for 1895, Relating to Births, Marriages, Deaths and Divorces. New Haven: Printed by Order of the Legislature. 1897.

Elementary Bandaging and Surgical Dressing, with Directions concerning the Immediate Treatment of Cases of Emergency for the Use of Dressers and Nurses. By Walter Pye, F.R.C.S., Late Surgeon to St. Mary's Hospital. Revised and in part rewritten by G. Bellingham Smith, F.R.C.S., Surgical Registrar, Guy's Hospital. Seventh edition. Philadelphia: W. B. Saunders. 1897.

Original Articles.

A STUDY OF THE BLOOD IN RICKETS.¹

BY JOHN LOVETT MORSE, A.M., M.D., BOSTON.

THE blood of infants under two years differs in certain of its characteristics from that of adults. The number of red corpuscles is about the same or a little larger, averaging a little over 5,000,000 per cubic millimetre. The number of white corpuscles per cubic millimetre is somewhat larger, averaging from 10,000 to 12,000. The relative proportions of the various forms of leucocytes are also considerably different. The limits, as given by Gundobin, are as follows:

Small mononuclear	50-70 per cent.
Large mononuclear	6-14 "
Polynuclear neutrophiles	28-40 "
Eosinophiles	1-10 "

That is, the proportion of mononuclear, or unripe forms, is about three times as great as in adult life, while that of the polynuclear neutrophiles, or over-ripe form, is only half as large. The mononuclear cells, moreover, are not merely lymphocytes but vary much not only in the size of the cell as a whole but also in the size of the nucleus and in the amount of protoplasm. Finally, an increase in the number of eosinophilic cells, even if considerable, seems to be of less significance.

Anemia of various sorts is very common in children. It develops more easily and more frequently as the result of various morbid conditions and diseases in them than in adults. This is because the tissue changes in them are more rapid as the old tissues have not only to be nourished and replaced but new ones formed. Hence any disturbance of nutrition is more serious and results in more rapid and significant changes in the blood.

The classification of the anemias of children is at best a vexed one. That of Monti is the most complete, but seems unnecessarily complicated. They, as those of adults, may be roughly divided into the primary and secondary, the primary being subdivided into simple anemia, chlorosis and pernicious anemia. Chlorosis with its typical symptom-complex and blood is not a disease of early childhood. Warner, however, has noted that "in the simple anemias of childhood the percentage of hemoglobin is diminished to a much greater extent than that of the red globules." I have also noted this in the anemia secondary to various diseases. Although cases of the so-called progressive pernicious anemia have been reported in young children, they are all open to criticism, and it is very doubtful if the condition occurs in them. The simple and secondary anemias may be divided into the mild and severe forms (anemia levis and anemia gravis). In the former the diminution in the specific gravity, hemoglobin, and number of erythrocytes, is slight, and the red corpuscles show non-histological changes. In the latter, the diminution in the specific gravity, hemoglobin, and number of red corpuscles, is marked and the histological changes in the red cells are often considerable. The differences, however, are merely in degree, and only show a greater or less amount of disturbance of the blood-forming organs. Either may or may not be accompanied by leucocytosis. In all but the mild anemia without leucocytosis the

spleen may be enlarged. It is to these cases that the term "splenic anemia" has been applied. They do not merit a special name, however, as there is nothing characteristic in the blood condition, and an enlarged spleen may be associated with a normal condition of the blood.

Much confusion exists concerning the so-called anemia infantum pseudo-leukemica. The description of this blood condition as given by Luzet and Alt and Weiss, is as follows: Constant diminution in number of erythrocytes; constant more or less marked diminution in hemoglobin; poikilocytosis; very many nucleated red cells mostly of abnormal form and many showing karyokinetic figures; polychromatophilia of the nucleated red cells and of many of the non-nucleated; pretty marked leucocytosis, always polymorphous. In addition there is always splenic tumor and more or less enlargement of the liver. Those who consider this blood condition characteristic are divided as to the limitations of the disease. Some, who consider it always primary, would rule out those cases in which it develops secondary to rickets, syphilitic, or other anemias, while others would include them. Others think that there is nothing characteristic in the blood condition, but that it is merely a very severe anemia, and not typical of any disease. Fischl has found the same type of blood in cases of rickets both with and without splenic enlargement. Moreover, cases of progressive anemia with enlarged liver and spleen do not always show this condition of the blood. Whether the condition known as anemia infantum pseudo-leukemica is to be considered as a separate disease or as merely a severe form of anemia gravis with leucocytosis must therefore be left for the future to determine.

It is generally recognized that leucocytosis develops more quickly and to a higher degree in children than in adults. While in adults the increase of white cells is almost entirely in the polynuclear neutrophiles, this is not the case in children. In them the leucocytosis is sometimes due to the increase of lymphocytes, sometimes to that of the large mononuclear forms, sometimes to that of the polynuclear neutrophiles, and sometimes even to that of the eosinophiles. According to Weiss, the lymphocytes are much increased proportionately in affections of the gastro-enteric tract, while the mononuclear cells of all sorts, as well as the transition forms, are proportionately increased in those of the respiratory tract. When there are complicated tissue changes and severe organic disturbances the proportions of the various forms of leucocytes show wide variations. He concludes that the proportions of the leucocytes correspond to certain tissue conditions and alterations and are thus characteristic for certain diseases, only in so far as quite definite tissue changes occur in these diseases. As the same pathological changes occur in many diseases, and different ones in the same disease, it is evident that the same histological blood condition is not always to be found in the same disease.

Monti has found that in normal children there is a constant relation between the specific gravity of the blood and the amount of hemoglobin. They vary directly. This relation is not constant in disease, however, and may vary in various ways.

Although the blood must have been examined in many cases of rickets, the literature of the subject is very meagre. No work worthy of mention seems to

¹ This paper will appear in the Boston City Hospital Medical and Surgical Reports, Eighth Series.

have been done in this direction before the beginning of the present decade. Since then, however, several observers have reported short series of cases, although no one seems to have undertaken a systematic investigation of the subject.

Monti found all the forms of anemia described by him in his classification in rhachitis. As a rule, he found the more severe forms in the severe cases. No definite connection between the clinical course of the cases and the condition of the blood could be made out, however. A greater proportion of the severe than of the mild forms showed splenic tumor. A greater proportion of the cases, with splenic tumor, showed leucocytosis than did those without. Certain cases with very large spleens showed no leucocytosis, however, and others without splenic enlargement showed a high grade. He concludes that "rickets as such does not cause any peculiar anemia, but that according to the severity of the rhachitic process and the associated involvement of the blood-forming organs very different forms and gradations of chronic anemia may occur."

Felsenthal examined the blood in 12 cases of rhachitis between the ages of nine months and two years, nine of which were mild cases with little or no enlargement of the spleen, while three were severe and had large, hard spleens. He obtained the same results in all. The number of red corpuscles was normal or almost normal, and there was no evident relation between the number of corpuscles and the severity of the case. The hemoglobin was diminished in all cases and always to a greater extent than the red corpuscles. The number of white corpuscles was always increased. He considered the oligochromemia as the most striking feature. He found that the red corpuscles often showed a considerable variation in size, and that nucleated forms, mostly normoblasts, and never very numerous, occurred in the severe cases. The majority of the white corpuscles were small and large mononuclear.

Weiss examined the blood in six cases. He found that all cases of severe rhachitis show a typical leucocytosis, the principal part of which is to be attributed to an increase of the mononuclear cells. The transition forms are also numerous, so that the polynuclear cells appear relatively diminished.

Gundobin found the same condition in the blood of rickets as that of other forms of retarded development. He concludes that rickets as rickets causes no peculiar pathological change in white cells, and that any change in them is dependent on concurrent involvement of the internal organs.

Luzet thinks that the blood in rickets associated with splenic enlargement may show all stages from mild anemia to leukemia. He thinks that the splenic tumor causes leucocytosis, increases the anemia, and makes the prognosis more gloomy.

Rotch reports the results of the examination of the blood in two cases of rhachitic anemia, one without and one with splenic tumor. The diminution of red corpuscles and of hemoglobin was more marked in the latter. It showed no leucocytosis, however, while the former did.

Hock and Schlesinger have found that the specific gravity of the blood in rickets is entirely independent of the severity of the rhachitic process, but varies with the anemia. Felsenthal and Bernhard have also shown that it varies with the amount of hemoglobin.

I have examined the blood in twenty cases of active, uncomplicated rickets in infants under two years of age. The blood was in every case taken from the lobe of the ear, and examined with a Thoma-Zeiss apparatus. It was diluted (1-200) with a three-per-cent. salt solution colored with methylene blue. The red corpuscles in one-tenth of a cubic millimetre and the white corpuscles in two cubic millimetres were counted. The hemoglobin was estimated with a von Fleischl instrument. Cover-slips were in all cases made at the same time, hardened in equal parts of alcohol and ether, and stained with Ehrlich's "triple stain." A differential count of at least 500 white corpuscles was then made, the classification recommended by Ehrlich being used. As far as possible the blood was taken about noon, and in most cases about three hours after food. The cases may be roughly divided into three groups according to the severity of the process; those in which the manifestations are mild, those in which they are more severe, but in which there is no splenic enlargement, and those in which there is splenic tumor. The first group comprises nine cases; the second, four; and the third, seven. The data of the individual cases are as follows:

MILD CASES.

CASE I. Male, negro. Eight months.

Breast for six weeks. Mellin's food since.

Marked sweating of head for two months. Always little cough. Bowels usually regular.

W. D. and N. Flabby. Holds up head. Head of good shape. Anterior fontanelle widely open. No teeth. Sits alone feebly with marked kyphosis of weakness. Moderate rosary. Moderate retraction of ribs at diaphragm with flaring below. Heart and lungs normal. Abdomen large but soft. Liver normal. Spleen not palpable. No enlargement of epiphyses. No glandular enlargement.

Hemoglobin	60 per cent.
Red corpuscles	4,170,000
White corpuscles	9,600
Small mononuclear	34 per cent.
Large mononuclear	4 "
Polynuclear neutrophiles	61 "
Eosinophiles	1 "

No irregularity in size or form of red corpuscles.

CASE II. Female, Irish. Seven months.

Breast for three months. Then Horlick's Malted Milk.

Head sweats. Restless at night. Tendency to diarrhea.

F. D. and N. Flabby. Pale. Holds up head. Head normal. No teeth. Sits alone feebly with moderate kyphosis of weakness. Moderate rosary. Heart and lungs normal. Abdomen full and soft. Liver and spleen normal. Slight enlargement of epiphyses at wrists. Slight general glandular enlargement.

Hemoglobin	57 per cent.
Red corpuscles	4,200,000
White corpuscles	9,300
Small mononuclear	36 per cent.
Large mononuclear	3 "
Polynuclear neutrophiles	60 "
Eosinophiles	1 "

No irregularity in size or shape of red corpuscles.

CASE III. Female, negro. Seven months.

Breast for five months. Condensed milk since.

Head sweats. Rolls head. Kicks off clothes. Vomits occasionally.

Large, fat child. Head normal. No teeth. Sits

alone with fairly straight back. Slight rosary. Heart and lungs normal. Abdomen little, full and tense. Liver and spleen normal. Slight enlargement of epiphyses at wrists. Little bowing of tibiae. Slight general glandular enlargement.

Hemoglobin	60 per cent.
Red corpuscles	5,048,000
White corpuscles	14,770
Small mononuclear	61 per cent.
Large mononuclear	4 "
Polynuclear neutrophiles	33 "
Eosinophiles	2 "

Moderate variation in size of red corpuscles, many being large. No poikilocytosis. One normoblast seen in two slides. Several of the large mononuclear leucocytes very large and containing a very large nucleus.

CASE IV. Male, Irish. Thirteen months.

Breast for ten months. Now arrow-root and milk.

Pertussis at seven months. Sits, creeps, and stands alone.

W. D. and N. Flabby. Pale. Head a little large. Fontanelle normal. Six teeth. General kyphosis of weakness. Moderate rosary. Heart and lungs normal. Abdomen soft and not distended. Liver and spleen normal. Considerable enlargement of epiphyses at wrists. No glandular enlargement.

Hemoglobin	67 per cent.
Red corpuscles	4,936,000
White corpuscles	18,800
Small mononuclear	24 per cent.
Large mononuclear	14 "
Polynuclear neutrophiles	58 "
Eosinophiles	4 "

CASE V. Female, negro. Thirteen months.

Breast off and on. Mellin's Food for eight months. Then milk. Also a little "table food."

Never well. Very fussy. Head sweats a good deal. Cannot creep or stand.

W. D. and N. Flesh firm. Head rather large, but of fair shape. Fontanelle three-quarters of an inch square. No teeth. Sits almost straight. Moderate rosary. Heart and lungs normal. Abdomen large and rather tense. Large umbilical hernia. Liver and spleen not enlarged. Moderate enlargement of epiphyses at wrists. Slight knock-knee. Some general glandular enlargement.

Hemoglobin	48 per cent.
Red corpuscles	5,024,000
White corpuscles	17,900
Small mononuclear	47 per cent.
Large mononuclear	8 "
Polynuclear neutrophiles	44 "
Eosinophiles	1 "

Very slight variation in size and shape of red corpuscles.

CASE VI. Male, Irish. Twenty-two months.

Still on breast. General diet since fourteen months. Always well. Does not stand.

F. D. and N. Flabby. Pale. Frontal and parietal eminences large. Fontanelle one-half inch square. Ten teeth. Sits with fairly straight back. Marked rosary. Slight retraction at diaphragm. Heart and lungs normal. Abdomen, liver and spleen not enlarged. Cannot stand. Epiphyses at wrists, and ankles much enlarged. Anterior bowing of femora and outward of tibiae. No glandular enlargement.

Hemoglobin	70 per cent.
Red corpuscles	5,144,000
White corpuscles	10,700
Small mononuclear	52 per cent.
Large mononuclear	4 "
Polynuclear neutrophiles	42 "
Eosinophiles	2 "

No variation in size or shape of red corpuscles.

CASE VII. Male, negro. Seventeen months.

Still on breast. General diet since twelve months.

Always fairly well. Head sweats. Fussy.

F. D. and N. Flabby. Head rather large. Fontanelle nearly closed. Six teeth. Sits fairly straight. Moderate rosary. Heart and lungs normal. Abdomen rather large but soft. Small umbilical hernia. Liver and spleen normal. Cannot stand. Epiphyses at wrists large. Slight bowing of tibiae. Slight general glandular enlargement.

Hemoglobin	64 per cent.
Red corpuscles	5,102,000
White corpuscles	14,000
Small mononuclear	49 per cent.
Large mononuclear	6 "
Polynuclear neutrophiles	43 "
Eosinophiles	2 "

No variation in size or shape of red corpuscles.

CASE VIII. Female, negro. Eight months.

Condensed milk, one month; cow's milk, three months; malted milk, four months.

Head sweats a great deal. Sleeps poorly. Diarrhea for long time.

F. D. and N. Rather flabby. Head normal. No teeth. Cannot sit alone. Moderate rosary. Heart and lungs normal. Abdomen not enlarged. Liver and spleen normal. Epiphyses at wrists enlarged. Tendency to knock-knee. No glandular enlargement.

Hemoglobin	67 per cent.
Red corpuscles	4,840,000
White corpuscles	10,200
Small mononuclear	53 per cent.
Large mononuclear	4 "
Polynuclear neutrophiles	41 "
Eosinophiles	2 "

A very little variation in size, but none in shape of red corpuscles.

CASE IX. Male, negro. Fourteen months.

Never nursed. Oatmeal and milk. Then general diet.

Head sweats. Restless at night. Always little cough. Constipation. Weak. Tries to stand.

F. D. and N. Head large, flat on top. Anterior fontanelle not widely open. Two teeth. Back straight. Marked rosary. Sternum prominent. Marked drawing-in at diaphragm. Heart and lungs normal. Abdomen large and soft. Liver and spleen normal. Epiphyses at wrists considerably enlarged. Knock-knee. No glandular enlargement.

Hemoglobin	62 per cent.
Red corpuscles	5,528,000
White corpuscles	9,000
Small mononuclear	32 per cent.
Large mononuclear	16 "
Polynuclear neutrophiles	51 "
Eosinophiles	1 "

A good deal of variation in the size of red corpuscles. Numerous microcytes and macrocytes. Moderate poikilocytosis. Numerous very large mononuclear cells with large, pale nucleus and wide, pale protoplasm.

SEVERE CASES.

CASE X. Female, Irish. Six months.

P. D. and N. Pale. Craniotabes. Moderate rosary. Heart and lungs normal. Abdomen large and soft. Liver extends four centimetres below costal border. Spleen not palpable. Epiphyses at wrists large. No glandular enlargement.

Hemoglobin	65 per cent.
Red corpuscles	4,704,000
White corpuscles	13,800
Small mononuclear	48 per cent.
Large mononuclear	4 "
Polynuclear neutrophiles	48 "
Eosinophiles	0 "

Moderate variation in size of red corpuscles. Slight poikilocytosis.

CASE XI. Male, Italian. Two months.
Condensed milk.

Small and emaciated. Skin dry. Pale. Sutures open and bones movable. Slight rosary and retraction at diaphragm. Heart and lungs normal. Abdomen soft. Liver and spleen normal. No enlargement of epiphyses. No glandular enlargement.

Hemoglobin	52 per cent.
Red corpuscles	3,508,000
White corpuscles	9,200
Small mononuclear	69 per cent.
Large mononuclear	5 "
Polynuclear neutrophiles	25 "
Eosinophiles	1 "

Marked variation in size of red corpuscles. Macrocytes much more numerous than microcytes. Marked poikilocytosis. Three macroblasts and two normoblasts seen in counting 500 whites.

CASE XII. Male, Italian. Nineteen months.
Breast for a year. General diet since.

Sweats a good deal. Diarrhea for a month. Quiet. Sits alone. Cannot creep or stand.

P. D. and N. Much hair. Pale. Head rather large, but not abnormal in shape. Anterior fontanelle open, one-half inch in each diameter. Four teeth. Marked general kyphosis, not disappearing on suspension. Marked rosary. Heart and lungs normal. Abdomen very large, tense and tympanitic. Liver and spleen normal. Epiphyses at wrists large. Large glands in groins only.

Hemoglobin	67 per cent.
Red corpuscles	5,296,000
White corpuscles	7,200
Small mononuclear	29 per cent.
Large mononuclear	17 "
Polynuclear neutrophiles	53 "
Eosinophiles	1 "

Slight variation in size of red corpuscles. Occasional microcyte and macrocyte. A very little poikilocytosis. Numerous very large mononuclear white cells.

CASE XIII. Male, negro. Two years.

Brought for "general weakness." Head sweats. Tendency to looseness of bowels. Sits alone. Cannot creep or stand.

P. D. and emaciated. Head large and forehead square. Anterior fontanelle open, an inch each in diameter. Ten teeth. General kyphosis of weakness. Pigeon breast. Marked rosary. Slight retraction of chest at diaphragm. Heart and lungs normal. Very large abdomen.

Umbilical hernia. Liver and spleen normal. Epiphyses at wrist large. Inguinal glands enlarged, others not.

Hemoglobin	64 per cent.
Red corpuscles	4,604,000
White corpuscles	5,500
Small mononuclear	39 per cent.
Large mononuclear neutrophiles	45 "
Eosinophiles	1 "

Very little variation in size and none in shape of red corpuscles.

CASES WITH SPLENIC TUMOR.

CASE XIV. Female, Irish. Nine months.
Breast and general diet.

Constipation. Losing weight. Restless at night. Kicks off clothes.

Head sweats. Sits alone.

F. D. and N. Flabby. Rather pale. Parietal eminences very large, frontal somewhat so. Fonta-

nelle almost closed. No teeth. Sits straight. Slight rosary. Heart and lungs normal. Abdomen little full. Liver extends an inch below costal border. Spleen just palpable. Epiphyses at wrists a little large. No glandular enlargement.

Hemoglobin	77 per cent.
Red corpuscles	4,724,000
White corpuscles	22,000
Small mononuclear	63 per cent.
Large mononuclear	4 "
Polynuclear neutrophiles	31 "
Eosinophiles	2 "

A little variation in size and shape of red corpuscles.

CASE XV. Male, Norwegian. Twenty months.
Always cow's milk. New fair diet.

Measles at one year. Very few digestive symptoms. Constipation. Sat up at nine months. Just beginning to creep. Doesn't stand. Brought because he cries when stood on feet. Not tender to touch. F. D. and N. Flabby. Pale. Large head. Fontanelle widely open. Sixteen teeth. Sits with marked kyphosis in lower dorsal region, which is only partially obliterated on suspension. Small chest. Marked rosary. Heart and lungs normal. Abdomen large and soft. Liver large. Spleen palpable. Epiphyses enlarged at wrists and ankles. Anterior and lateral bow-legs. General glandular enlargement.

Hemoglobin	73 per cent.
Red corpuscles	4,448,000
White corpuscles	14,400
Small mononuclear	49 per cent.
Large mononuclear	6 "
Polynuclear neutrophiles	40 "
Eosinophiles	5 "

Moderate variation in size of red corpuscles, but no microcytes or macrocytes. Very little poikilocytosis.

CASE XVI. Male, Italian. Nine months.
Breast and general diet.

Measles and diphtheria at six months, followed by running ear. Subject to attacks of vomiting and diarrhea. Head sweats badly. Sits alone.

F. D. and N. Flabby. Pale. Large square head. Fontanelle very widely open but not tense. No teeth. Back straight. Small chest. Marked rosary. Heart and lungs normal. Abdomen large and tense. Liver normal. Spleen palpable. Epiphyses at wrists and ankles enlarged.

No glandular enlargement.

Hemoglobin	60 per cent.
Red corpuscles	4,068,000
White corpuscles	14,500
Small mononuclear	34 per cent.
Large mononuclear	3 "
Polynuclear neutrophiles	58 "
Eosinophiles	7 "

No variation in size or shape of red corpuscles.

CASE XVII. Female, Irish. Fifteen months.
Now on milk and cracker only.

Brought because of "weakness in legs." Sits alone. Doesn't creep. F. D. and N. Pale. Head a little large. Fontanelle almost closed. Seven teeth. Back straight. Marked rosary. Heart and lungs normal. Abdomen full. Liver normal. Spleen distinctly palpable. Large epiphyses at wrists. Legs held loosely and rotated outward at hips. Tendency to talipes varus. No spasm. Knee-jerks present and equal. No glandular enlargement.

Hemoglobin	64 per cent.
Red corpuscles	4,336,000
White corpuscles	11,900
Small mononuclear	39 per cent.
Large mononuclear	6 "
Polynuclear neutrophiles	48 "
Eosinophiles	7 "

Moderate variation in size of red corpuscles. A few macrocytes and numerous microcytes. Slight poikilocytosis.

CASE XVIII. Male, Irish. Five months.

Never gained. Cries constantly. Sleeps very little. Frequent vomiting. Constipation.

Small but not much emaciated. Marked pallor. Head negative; can hold it up. Cannot sit alone. Marked rosary. Systolic murmur over whole præcordia. Heart otherwise normal. A few râles here and there in both chests. Abdomen lax. Liver normal. Spleen palpable below costal border, as large as last phalanx of thumb. Epiphyses at wrists slightly enlarged. No glandular enlargement.

Hemoglobin	57 per cent.
Red corpuscles	4,519,000
White corpuscles	15,900
Small mononuclear	44 per cent.
Large mononuclear	4 "
Polynuclear neutrophiles	47 "
Eosinophiles	5 "

A very little variation in size and shape of red corpuscles. One normoblast seen in counting five hundred white corpuscles.

CASE XIX. Female, Russian. Twenty months.

Breast and patent foods at first. Now general diet. Always digestive disturbances. Very restless at night. Sits and stands; cannot walk.

F. D. and N. Flabby. Pale. Large, square, flat head. Anterior fontanelle nearly closed. Eleven

teeth. General kyphosis of weakness. Pigeon breast. Marked retraction at diaphragm. Very marked rosary. Heart and lungs normal. Abdomen large and soft. Liver not enlarged. Spleen palpable below costal border, seven centimetres laterally and three centimetres vertically. Marked enlargement of epiphyses at wrists. Moderate bowing of both femora and tibiae. No glandular enlargement.

Hemoglobin	68 per cent.
Red corpuscles	5,518,000
White corpuscles	15,200
Small mononuclear	51 per cent.
Large mononuclear	5 "
Polynuclear neutrophiles	40 "
Eosinophiles	4 "

Considerable variation in size of red corpuscles. Numerous macrocytes. Moderate poikilocytosis. Occasional normoblasts.

CASE XX. Female, Irish. Seventeen months.

Condensed milk and barley-water.

Pale for a long time. Rapid loss of flesh in last three months.

Tumor in abdomen noted two months ago, as large then as now. Just beginning to sit up alone. No vomiting. Constipation.

F. D. and emaciated. Marked pallor with yellowish tinge. Fontanelle not closed. Four teeth. Rosary. Heart and lungs normal. Abdomen very full and tense. Umbilical hernia. Liver not enlarged. Spleen fills left half of abdomen, reaching nearly to median

No.	Age in Months.	Type of Disease.	Hemoglobin.*	Erythrocytes.	Leucocytes.	Small Mononuclear.*	Large Mononuclear.*	Polynuclear Neutrophiles.*	Eosinophiles.*	Morphology of Erythrocytes.

20	17	Spleen very large.	60	3,556,000	12,400	28	10	55	7	Marked variation in size. Moderate poikilocytosis. Numerous nucleated forms.

* The figures in these columns represent percentages.

line and to within half an inch of anterior superior spine. No ascites. Epiphyses enlarged. No glandular enlargement. Purpuric spots on abdomen. Urine negative.

Hemoglobin	60 per cent.
Red corpuscles	3,556,000
White corpuscles	12,400
Small mononuclear	28 per cent.
Large mononuclear	10 "
Polynuclear neutrophiles	55 "
Eosinophiles	7 "

Marked variation in size of red corpuscles. Many macrocytes and microcytes, the former being the more numerous. Moderate poikilocytosis. Moderate number of nucleated red corpuscles, megaloblasts being the most common form. Occasionally free nuclei. No abnormal forms of white corpuscles.

The results of the blood examinations are more evident, perhaps, in the table on the preceding page.

An analysis of these cases shows that the number of red corpuscles was in all cases normal or but slightly diminished; that the percentage of hemoglobin was always diminished, and always proportionately more so than that of the red corpuscles; that there was a leucocytosis in a little more than half the cases; that this leucocytosis occurred more frequently in these cases with splenic tumor than in those without; that the amount of the leucocytosis was independent of the presence, or absence, or size, of the splenic tumor; and that the histological changes in the red corpuscles increased, as a rule, with the severity of the case, being most marked in those with the splenic tumor.

The approximately normal number of red corpuscles and the absolutely and relatively diminished proportion of hemoglobin agrees with the results obtained by Felsenthal. It must be remembered, however, as has already been noted, that this condition is not an uncommon one in the anemias of childhood.

The results as regards the white corpuscles do not agree with those of Felsenthal, who found a leucocytosis in every case, but rather corroborate Monti's conclusions that leucocytosis may or may not be present, and that it is more frequent in the cases with splenic tumor. They also confirm his observation that certain cases with very large spleens have no leucocytosis, as the case with the largest spleen had but little more than the normal number of white corpuscles. The average of the different forms of leucocytes in the nine cases without leucocytosis gives the following proportions, which are somewhat different from those given by Gundobiu for normal blood:

Small mononuclear	43 per cent.
Large mononuclear	8 "
Polynuclear neutrophiles	47 "
Eosinophiles	2 "

The average proportions in the eleven cases with leucocytosis, as well as in the six cases with enlarged spleens, are:

Small mononuclear	45 per cent.
Large mononuclear	5-6 "
Polynuclear neutrophiles	45 "
Eosinophiles	4-5 "

That is almost the same as in the cases without leucocytosis.

These results do not agree with those of Weiss and Felsenthal, who found the increase in the mononuclear and transition forms, but rather with Weiss's general statement that when there are complicated tissue changes the increase may be in any or all of the different forms of leucocytes. It is noticeable that eosinophilic cells are considerably more numerous in the

cases with splenic tumor. The association of nucleated forms and of variations in the size and shape of the red corpuscles with an almost undiminished number is of interest.

CONCLUSIONS.

The results obtained in these cases, together with those obtained by others, seem to justify the following conclusions: Most cases of rickets are accompanied by anemia. This anemia may be of any form and of any grade of severity. The severity of the anemia varies in a general way with the severity of the process. The most common form is that in which the number of red corpuscles is normal or nearly normal, and the percentage of hemoglobin both absolutely and relatively diminished. The anemia may or may not be accompanied by leucocytosis. Leucocytosis occurs more frequently in the cases with splenic tumor than in those without. It may be due to an increase in any or all of the varieties of white corpuscles. The specific gravity varies with the amount of hemoglobin. Finally, there is no form of anemia found in rickets which may not be found in other conditions, and no form of anemia found in other conditions which may not be found in rickets.

A REPORT ON THE BACTERIOLOGICAL INVESTIGATIONS OF THREE HUNDRED AND TWELVE CASES OF SURGICAL INFECTION.¹

(FROM THE SURGICAL WARDS AND OUT-PATIENT DEPARTMENT OF THE BOSTON CITY HOSPITAL.)

BY JOSEPH JAMES CURRY, M.D.,
Assistant in Pathology, Harvard Medical School.

IN this paper, in addition to the bacteriological report, the results of the clinical study of the cases have been presented as far as possible. Two hundred and fifty cases were from the wards and sixty-two from the Surgical Out-patient Department. The Out-patient Department cases occurred from September 1 to December 1, 1895, and the ward cases from January 1, 1896, to December 31, 1896.

The work was carried on under the direction of Prof. W. T. Councilman, in the Pathological Laboratory of the Boston City Hospital.

¹ This paper will appear in the Boston City Hospital Medical and Surgical Reports, Eighth Series.

METHODS OF STUDY.

The methods of study pursued were the same as those used by Wright and Stokes which they described at length in their report on the bacteriological investigations of autopsies, published in the sixth series of these reports.

Löffler's blood-serum mixture in slants (Dr. Mallory's modification) was used almost entirely. In the differentiation of typhoid and colon bacilli, and in several other cases, the usual special media were employed. In some of the cases inoculations of animals were also made.

ABSCESES.

One hundred and fifteen cases examined, with the following results:

Streptococcus pyogenes occurred 56 times.
Staphylococcus pyogenes aureus occurred 52 times.
Staphylococcus pyogenes albus occurred 29 times.
Bacillus pyocyaneus occurred 4 times.
Micrococcus lanceolatus occurred 2 times.
Bacillus diphtherie occurred 1 time.
Bacillus coli communis occurred 6 times.
Bacillus pyogenes fetidus occurred 1 time.
Bacillus typhi abdominalis occurred 1 time.
Gonococcus occurred 1 time.
Ameba coli occurred 1 time.
Undetermined bacteria occurred 3 times.

Of these 115 cases 78 were caused by a single organism and 37 were due to a mixed infection. Of these 78 cases in which pure cultures were obtained the streptococcus occurred in 31; the staphylococcus aureus in 32; the staphylococcus albus in 8; the bacillus coli communis in 3; the bacillus typhi abdominalis in 1; the micrococcus lanceolatus (pneumococcus) in 1; gonococcus in 1, and the ameba coli in 1. Of the 37 cases of mixed infection the streptococcus occurred in 25; the staphylococcus aureus in 20; the staphylococcus albus in 21; the bacillus coli communis in 3; the bacillus pyocyaneus in 4; the bacillus diphtherie in 1; the bacillus pyogenes fetidus in 1; the micrococcus lanceolatus in 1, and undetermined bacteria in 3.

It will be noticed that the streptococcus was found in these cases much more frequently than is usual in abscesses. In the pure infections the streptococcus occurred in 39 per cent., the staphylococcus aureus in 41 per cent., and the albus in about 10 per cent. This large percentage of streptococcus can be accounted for partly by the fact that by far the greater number of these cases occurred in the wards. Usually abscesses due to the staphylococci are of a milder nature so that they can be treated in the Out-patient Department; consequently it would be expected that in the cases severe enough to warrant admission to the hospital there would occur a relatively higher percentage of streptococci. That such is the fact will be seen by a study of the following cases: Of the 78 pure infections 18 occurred in Out-patient Department and 60 in the wards. Of the 18 out-patient cases the staphylococcus aureus occurred in 13; the staphylococcus albus in 4, and the streptococcus in 1.

Of the 60 ward cases the aureus occurred in 20, the albus in 4, and the streptococcus in 30. In the out-patient cases it will be seen that only a little over 5 per cent. were due to the streptococcus, while in the ward cases the streptococcus occurred in 50 per cent.

Of the 37 cases of mixed infection 5 were out-patient and 32 ward cases. In the 5 out-patient cases

the streptococcus occurred twice, the albus twice, and the aureus once.

In the 32 ward cases the streptococcus occurred in 23, the aureus in 18, and the albus in 19. The mixed infections show also a relatively higher percentage of streptococci in the ward cases, about 72 per cent., while the out-patient cases show 40 per cent. The combination of the mixed infections in which the streptococcus occurred are as follows: Streptococcus with aureus, 11; with albus, 8; with the diphtheria bacillus, 1; with other bacteria, 5. The mixed infections were, as a rule, more severe than the pure infections. Occasionally, however, the different bacteria antagonize one another in mixed infections, producing a milder inflammation. The combination of the streptococcus and aureus produced the most severe symptoms.

Of the cases of abscess in which other than the staphylococci and streptococci occurred there were a number which are deserving of mention. The diphtheria bacillus occurred once, with the streptococcus in an abscess of the back following antitoxin injection. This abscess showed no special features and healed readily. The colon bacillus was found three times in mixed cultures. The pure cultures were from abscesses of gall-bladder, kidney and pelvis. The mixed cultures were obtained from three pelvic abscesses.

The typhoid bacillus was found once in pure culture in an abscess of the gall-bladder. The gonococcus occurred once in a labial abscess. The ameba coli was found pure in a case of liver abscess.

The pyocyaneus occurred in four cases, but in each instance with one or more of the pyogenic cocci.

The three cases of abscess due to the colon alone were mild. The abscess of the kidney due to colon bacilli discharged for a long time. In this case, however, there was a mixed infection after operation. The wound could not be closed, and the drainage opening gave entrance to the pyogenic cocci.

Of the rarer abscesses that of the gall-bladder due to the typhoid bacillus is worthy of note. This abscess occurred in the third week of typhoid fever. The patient at the time was in too precarious a condition for surgical interference. The abscess was aspirated by Dr. A. L. Mason, and about three or four ounces of purulent fluid withdrawn, from which cultures were made. The patient made a good recovery, and was discharged after the usual time of typhoid convalescence.

The case of abscess of the liver due to ameba coli is uncommon in this part of the country. Cultures from abscess showed no growth of bacteria. The diagnosis of the presence of ameba coli was made by fresh examination.

CARBUNCLES.

Three cases. In each case the staphylococcus aureus was obtained in pure cultures.

PUSTULES.

Six cases. All pure infections; the staphylococcus aureus occurred in four; the bacillus diphtherie in one; and the bacillus pyocyaneus in one.

FURUNCULOSIS.

Six cases (pure infections). The aureus occurred in four; the streptococcus in one; and the pyocyaneus in one.

FELONS.

Three cases of pure infection. The aureus occurred in each case.

MALIGNANT PUSTULE.

One case in which the staphylococcus citreus was found with the anthrax bacillus. This case will be reported fully under mixed infections.

CELLULITIS.

Thirty-five cases, of which 17 were pure infections and 18 mixed infections. The streptococcus was found in 19; the aureus in 16; the albus in 7; the pyocyaneus in 3; the micrococcus lanceolatus in 2; the megatherium bacillus in 1; and undetermined bacilli in 2.

Of the 17 pure infections the streptococcus occurred in 9; the aureus in 6; and the micrococcus lanceolatus in 2. In the 18 mixed infections the streptococcus occurred 10 times: 5 times with the aureus, 3 times with the albus, once with the pyocyaneus, and once with the albus and pyocyaneus. Of the remaining 8 cases of mixed infection the megatherium and albus occurred once, the albus and aureus in 2, the aureus and pyocyaneus in 1, and the aureus and undetermined bacilli in 2.

In the pure infections the streptococcus produced the more marked symptoms with slower recoveries. Those due to the aureus were, as a rule, of milder character, though in several the symptoms were fully as marked as in the severe streptococcus cases. Even in the severer types of inflammation due to the aureus, they were, as a rule, of shorter duration than the streptococcus infections.

The cases due to the pneumococcus did not show any special severity.

In the mixed infections the streptococcus and aureus were the most severe. The presence of the pyocyaneus did not exercise any marked influence. The megatherium with the albus produced a rapid and intense inflammation. This case will be reported under mixed infections.

ERYSIPELAS.

Two cases. In each the streptococcus was obtained in pure culture.

DERMATITIS.

One case, in which the streptococcus and the albus were found.

BUBO.

Six cases. There were five of pure and one of mixed infection. Of the pure infections the streptococcus occurred in one, the aureus in one, and the albus in three. In the case of mixed infection the streptococcus and the albus.

ACUTE VESICULITIS.

One case, in which the gonococcus was found.

BONE.

Two cases of osteomyelitis of tibia and one case of acute periostitis were examined, and the staphylococcus aureus occurred in each case.

PYOSALPINX.

Six cases (tubes removed at operation). The streptococcus occurred in one, the aureus in one, the micrococcus lanceolatus in one, and the gonococcus in three. The clinical history of these cases is interesting. The

three due to gonococcus and the one due to the micrococcus lanceolatus made good recoveries. The case due to the streptococcus died of septicemia. The one due to the aureus was accompanied by pelvic abscess and recovery was very slow.

ACUTE ENDOMETRITIS.

Three cases. In each of these the streptococcus occurred in pure cultures. Two of these cases occurred after normal delivery and one after an abortion. In each case there were marked septic symptoms and slow recovery.

PERITONITIS.

One case. In this case the micrococcus lanceolatus and colon bacillus were found. Patient died in twenty-four hours after admission, with general fibrinous peritonitis.

GUMMA.

One case of gumma of arm. The skin was unbroken. Cultures taken after incision showed the aureus and albus, which were undoubtedly a contamination from the skin. The examination by cover-slip for Lustgarten's bacillus was negative.

CONJUNCTIVITIS.

Two cases. In one case the streptococcus and albus were found, and in the other the bacillus diphtheria. This latter case was especially severe, threatening destruction of the cornea, and was sent to contagious wards for antitoxin treatment.

INFECTED WOUNDS.

In one case of wound by bullet from revolver, the streptococcus and albus were found.

Wound from beef bone: one case, in which the staphylococcus aureus occurred.

Dog bite: one case, in which the albus and an unknown bacillus were found.

Insect bite: one case, in which occurred the staphylococcus citreus.

In these cases of infected wounds the bacteria were probably carried in from the skin.

ULCERS.

Thirteen cases of chronic ulcer of the leg were examined. In each case one or more of the pyogenic cocci were found, as might be expected on an exposed surface. These cases are reported, as they bring out several interesting facts.

In nine the pyocyaneus occurred, and in four the bacillus pyogenes fetides. The four cases in which the fetidus occurred were all extremely sluggish and stubborn to treatment. Under various dressings they showed no improvement. They were distinctly the worst class of ulcers that came to the Out-patient Department.

On the other hand, the pyocyaneus did not seem to exercise any deleterious effect on the ulcers. The green pus cleared up after a day or two and usually left the ulcer clean. There was no increased inflammation, and it seemed that the ulcers were benefited. A clean granulating surface was usually left behind. It is a curious fact that these cases of pyocyaneus infection occurred about the same time. On September 8th a patient came into the Out-patient Department with furunculosis of the arm in which the pyocyaneus was found. Before this no cases of pyocyaneus ulcers

were observed. Two days later three of the old chronic ulcers were surrounded by a green rim. The other six cases followed in a few days. Evidently the case of furunculosis was the source of this infection. Just how the pyocyaneus was conveyed to the ulcers was not found out.

It was noticed that under dressings of corrosive (wet) gauze the green pus cleared up in a day or two.

APPENDICITIS.

Fifty cases of appendicitis were examined. In most of these cases there was abscess formation. The cultures were taken from the abscess cavity immediately upon the opening of the abdomen. Where there was no abscess the culture was taken from the stump of the appendix. There were 28 cases in which mixed cultures were obtained, 20 in which pure cultures were found, and 2 showed no growth. Of the entire number, 12 patients (or 24 per cent.) died.

The streptococcus occurred in 15, the aureus in 1, and the colon bacillus in 46.

Of the 20 cases in which pure cultures were obtained the colon occurred in 19 and the streptococcus in 1. Of the 28 cases in which mixed cultures were obtained, streptococcus and aureus occurred in 1, the streptococcus and colon in 13, and the colon *plus* a variety of undetermined bacteria in 14.

In case of appendicitis where there is abscess formation, there are usually large numbers of bacteria of various kinds found. These probably come from the intestine, and many of them have no pathological significance.

Of the 12 fatal cases, the cultures taken at the time of operation showed in 7 pure colon, in 3 streptococcus and colon, in 1 colon and undetermined bacteria, and in 1 no growth occurred.

In this latter there was undoubtedly an error in taking the culture, as the case was that of a perforated gangrenous appendix.

Of the 38 cases of recovery, in 12 the colon was found in pure culture, in 1 the streptococcus in pure culture, in 1 the streptococcus and aureus, in 10 the streptococcus and colon, in 13 the colon *plus* undetermined bacteria, and in 1 no growth.

A study of the clinical records of these cases is interesting. Taking first the 38 cases of recovery, it was found that in the 12 cases from which pure colon was obtained 11 made good recovery, averaging 33 days in the hospital, and 1 was discharged relieved after 10 weeks. Of the 13 cases in which colon *plus* undetermined bacteria were found, 10 made good recovery, and 3 were slow, 1 of which was operated on a second time.

In this case the streptococcus was found at the second operation. Of the 12 cases in which the streptococcus occurred, one in which the streptococcus and aureus were combined made a slow recovery and was accompanied by pelvic abscess, for which a secondary operation was necessary. The one in which the pure culture was obtained was a case which had been operated on three months before, and which came in again for a third operation. In this case also the streptococcus was found at the secondary operation, but not in the primary operation. Only colon was found at time of primary operation. Of the remaining 10 cases in which the colon was combined with the streptococcus, in four the convalescence was slow, and two of these came to secondary operation; three made good recovery,

and three are now in the wards, having been operated on within the past week. The case showing no growth made good recovery, in less than four weeks.

In 7 of the 12 fatal cases, pure cultures of the colon bacillus were found. Of these 2 died on the day of operation, 1 within 24 hours, 1 in 48 hours, and 3 in from 5 to 8 days. In all 7 there had been perforation, and in 3 at time of operation there were symptoms of general peritonitis and collapse.

In the case in which the colon bacillus *plus* undetermined bacteria were found, death occurred from general peritonitis in two days. The case from which no growth was obtained had a perforated gangrenous appendix, and death followed on the second day after operation. Of the three cases in which the streptococcus occurred, one had made good recovery for two weeks, then suddenly developed secondary abscess and general peritonitis; death two days later. The other two streptococcus cases died in five and seven days, with symptoms of general infection. There was only one autopsy. This was on a case in which at time of operation the cultures showed colon bacilli, but no streptococci. The autopsy revealed a general purulent peritonitis, from which both in cover-slip preparations and in the cultures numerous streptococci were found.

The study of these cases brings about this fact, that the absence of the streptococcus from cultures taken at time of operation, where there has been perforation, is of negative value. That it may be an etiological factor is shown by the three cases mentioned above, in which at time of primary operation no streptococci were found, but subsequently they were obtained, once at the autopsy and twice at secondary operations. It is probable that in the presence of the large number of colon and other bacteria usually present in such cases the streptococcus could not grow.

Out of a total of 15 cases of streptococcus there were 3 deaths and 6 slow recoveries, in 4 of which, later, secondary operations were necessary. Three had normal convalescence and 3 were operated on too recently to give full report.

Leaving out the 3 cases now in the wards, we have a death-rate of 25 per cent., and 4 out of the 12 cases, or 33 per cent., having secondary abscess formation demanding another operation.

When we consider the cases in which the streptococcus was absent in cultures we find, out of a total of 35 cases, 9 deaths, 5 slow recoveries, and 21 of normal convalescence. In one of the fatal cases the streptococcus was found at autopsy. This case died 8 days after operation. Of the remaining 8 cases 6 died within 3 days, 1 in 5, and 1 in 6 days. The fact that in every one of these nine cases there had been perforation explains this high death rate due apparently to the colon bacillus. That the colon bacillus can produce a fatal peritonitis is undoubtedly true, but it is uncommon and only when they are in immense numbers. Welch, in his article "Bacteria of Surgical Infection,"² does not regard the colon bacillus in cases of appendicitis as the primary organism. He says, "There is reason to believe that the highly resistant colon bacillus may survive in an inflamed part after the primary organism which started the trouble has died out or has been crowded out by the invader."

² Vol. i, Dennis's System of Surgery.

This view corresponds with our experience in these cases, and the bacteriological examination of cases of peritonitis which have come to autopsy corroborates it. It is rare to find a case of peritonitis due to the colon alone.

Out of the eight deaths mentioned above, six never rallied after the operation, and in the other two there was ample time and opportunity for a streptococcus invasion.

The probability is that in the cases of pure colon the inflammation was started by the streptococcus or some other of the ordinary pyogenic bacteria, and the failure to grow them in cultures was due to the presence of immense numbers of colon.

A careful study of these 50 cases cannot fail to impress us that the occurrence of the streptococcus brings a grave element into the prognosis. Of the cases which came to secondary operation the streptococcus was found in every instance, either at time of first or second operation. In the cases of recovery the streptococcus showed a higher percentage of long-drawn-out convalescence.

The results of the bacteriological investigations of appendicitis are far from being satisfactory. The study of these cases simply emphasizes the fact that the presence of the streptococcus is usually attended with symptoms of the severest type. There is a great variability in the virulence of the streptococci found here as well as in other inflammations. They may cause but slight disturbance, but are far more liable to result in a general peritonitis or septicemia.

In cases of perforation and abscess formation, it must be borne in mind that the absence from the cultures of the pyogenic cocci is of negative value.

OTITIS MEDIA.

Thirty cases, 24 pure infections, and 6 mixed infections. The streptococcus occurred in 14: 12 times in pure culture, and twice with aureus. The micrococcus lanceolatus five times, in pure culture. The capsule bacillus occurred in two: once in pure culture and once with the diphtheria bacillus. The aureus occurred five times: twice in pure culture, twice with the streptococcus, and once with the diphtheria bacillus. The albus in four: twice in pure culture, once with the diphtheria bacillus, and once with an unknown bacillus.

The Klebs-Löffler (bacillus diphtheriae) occurred four times: once in pure culture, once with the capsule bacillus, and once each with the aureus and albus. A large spore-bearing bacillus, closely resembling the anthrax bacillus in its growth and size, was found in two cases: once in pure culture from the mastoid cells and once from middle ear with the albus. This bacillus was not pathogenic for guinea-pigs or rabbits. The writer was unable to identify it.

Of these 30 cases of acute otitis, 14 developed a severe mastoiditis which necessitated operation. Cultures were taken from these latter from the mastoid cells as well as from the middle ear. In these mastoid cases the streptococcus occurred in 10: eight times in pure culture and twice with the aureus. The micrococcus lanceolatus occurred in two, in pure culture; the diphtheria bacillus with capsule bacillus in one, and the large spore-bearing bacillus in one.

There were five deaths in the 30 cases. In these cases the streptococcus occurred in one, the pneumococcus (micrococcus lanceolatus) in one, the aureus in

one, and the capsule bacillus in two, once pure and once combined with the diphtheria bacillus.

The capsule bacillus found in these cases resembled that of Friedländer, but differed from the Friedländer bacillus in that it always grew with capsule surrounding it, when cultivated on artificial media. There were also several minor points of difference. It apparently was identical with the capsule bacillus described by Mallory and Wright.³

Of the fatal cases, in the one due to the streptococcus, the patient died with symptoms of general infection within five days. In the case due to the aureus, a brain abscess followed, death resulting in three weeks after ear trouble began.

In these two cases the middle ear was the primary focus of the fatal infections. In the other three cases the ear trouble was secondary and death was due to other causes. In the two cases in which the capsule bacillus was found, one in which the diphtheria bacillus was found, the patient died of pneumonia and general infection with the micrococcus lanceolatus. At the autopsy the micrococcus lanceolatus was found in the lung, heart's blood, and kidney, but not in the middle ear. The capsule bacillus and the diphtheria bacillus were found in the middle ear, but nowhere else. There was no extension of ear trouble to the cranial cavity. In the other case of capsule bacillus death was due to fracture of the base of the skull. In the case of the micrococcus lanceolatus there was pneumonia and general infection. The ear trouble began during the course of the pneumonia. Of the 25 cases which recovered the streptococcus occurred in 13, the aureus in 4, the albus in 4, the micrococcus lanceolatus in 4, the bacillus diphtheriae in 3, and a large unknown bacillus in 1.

The cases in which the streptococcus occurred were, as a rule, the worst. This is illustrated by the fact that in the 14 streptococcus cases 1 died and 10 came to operation for mastoiditis, while only 3 made recovery without any severe symptoms.

Of the five cases in which the aureus was found, two recovered in one week. One in which the streptococcus was also found, recovered in six weeks; one accompanied by the streptococcus also recovered in three weeks; and one died with brain abscess.

Of the five cases in which the micrococcus lanceolatus was found, one died (death due to pneumonia and general infection), two came to operation for mastoiditis, and two made recovery in one and two weeks respectively. The two cases which came to operation recovered, one after five weeks and one after two weeks. The cases in which the diphtheria bacillus was found did not show any special symptoms, except the one in which the pure culture was found. This patient had been in the diphtheria wards, from which he had been discharged some time before his ear trouble began. It was several weeks after his discharge that he presented himself at the Out-patient Department with an acute otitis media. Bacteriological examination showed a pure culture of the diphtheria bacillus from the discharge from ear. Patient recovered without any unusual symptoms being observed.

Of the two cases in which the large unknown bacillus was found, the one which came to mastoid operation was discharged well in six weeks, the other in two weeks. The latter was accompanied by the albus; the culture was taken from the middle ear.

³ Centralblatt f. Bacteriologie, 1895.

It is a question whether this large bacillus had anything to do with the process. The cases in which the albus was found were all of a mild nature. It is probable that in several, at least, of these, the presence of the albus was due to contamination of swab from external ear.

Six of the 30 cases occurred during the course of acute diseases: three in the course of typhoid, and three in the course of pneumonia.

Of the three cases occurring during typhoid, two were in the third week and one in the second week of the disease. In the first two the streptococcus was found, and in the latter the micrococcus lanceolatus. Of the three cases occurring during pneumonia, in one the aureus and diphtheria bacillus was found on the third day of the disease. In the second case the micrococcus lanceolatus was found on the seventh day.

In the third case the capsule bacillus and bacillus diphtheria were found at the post-mortem examination. Patient complained of his ear just before death.

The conclusion to be drawn from a study of these cases is that the pyogenic cocci, especially the streptococcus, produce the severest forms of inflammation of the middle ear. While the pneumococcus may produce very severe inflammations and involve the brain or its coverings, still in the absence of pneumonia or other complications the case tends to recover readily.

EMPIYEMA.

Eighteen cases. Of these 16 were caused by a single organism and in 2 mixed cultures were obtained. The streptococcus occurred 8 times, the pneumococcus 9 times, the staphylococcus aureus once. In the cases where mixed cultures were obtained, in one, in which there was an accompanying pneumothorax, the streptococcus and a variety of undetermined bacteria were found. In the other case the culture was taken some time after operation, and the pyocyanus, the pneumococcus, and a number of other organisms were found.

Taking the 16 cases in which pure cultures were found, 8 were due to the pneumococcus, 7 to the streptococcus, and one to the staphylococcus aureus.

In the eight pneumococcus cases there was one death. This patient also had heart disease. Of the recoveries one combined with unresolved pneumonia was slow, extending over some months. The other six patients made good recovery.

The case due to the staphylococcus aureus was very slow, with marked constitutional disturbance. In the study of these cases we are impressed with the uniformly favorable course and termination of the cases due to the pneumococcus in the absence of complications. On the other hand, those due to the streptococcus have been as uniformly severe, with the high death-rate of 43 per cent.

MIXED INFECTIONS.

Of the cases of mixed infection deserving special mention those of the fetidus and pyocyanus in connection with chronic ulcers of the leg have been spoken of under ulcers. There are two others of interest.

The first is the case of cellulitis due to the staphylococcus albus and megatherium bacillus.

The history of the case: Patient a man about fifty years, in the employ of the health department of the

city of Boston. His work consisted in collecting garbage. Came into the Out-patient Department September, 1895, giving the following history: Scratched the back of his hand in some manner the day before. The scratch was not deep and not particularly painful and did not bother him any, and for the time he forgot all about it. That night noticed his hand was considerably swollen. This grew rapidly worse. Hand and forearm swelled considerably during the night and became very painful, so he could not sleep. Examination showed right hand and forearm very much swollen; back of hand red and tender; patient, though a strong man, looked very shaky. The hand was freely opened by Dr. Dwight; there was no pus. Cultures were taken from swollen edematous subcutaneous tissue. A wet corrosive dressing covering the hand and wrist applied. Patient advised to go into the hospital, but went home. Cultures showed staphylococcus albus and an unknown bacillus, which after cultivating on various media was identified as the megatherium. These cultures gave off a peculiar characteristic odor, that of stale swill. This bacillus was first discovered by DeBarry on the leaves of boiled cabbage. It is non-pathogenic. This sudden intense inflammation coming on a few hours after inoculation could hardly be due to the albus alone, which usually takes several days to produce any marked inflammation, and usually with the albus the process is mild. It is probable that the megatherium, though by itself non-pathogenic, played an important part in this case by markedly increasing the virulence of the albus.

The second case was that of the anthrax and staphylococcus citreus, in a case of malignant pustule of the neck. This case, a young man, a longshoreman by trade, came into the hospital in the service of Dr. H. L. Burrell, in February, 1896. The man at time of entrance had a temperature of 105°. Before the operation bacteriological examination of the fluid contained in the vesicles surrounding the eschar showed many of the characteristic anthrax bacilli. Cultures were made from the vesicles, from the subcutaneous tissue after removal of tumor, and from the tumor itself. From the vesicles and just under skin mixed growths of anthrax and citreus were obtained. From the depth of the wound after removal of tumor a pure culture of the citreus; no anthrax.

The first thing that struck the writer upon examining the cultures after eighteen hours' growth was that in all three there was apparently macroscopically a pure growth of the citreus. It was only on close inspection that a slight whitish ill-defined growth at bottom of tube was observed in two of the tubes. Microscopical examination showed this whitish growth to be anthrax. The staphylococci far outgrew the anthrax. The anthrax and citreus were finally obtained in pure cultures from the original mixed culture. It occurred to the writer upon observing that the citreus grew so profusely with mixed cultures, while the anthrax showed but slight growth, that there might be some antagonism between them. A series of experimental inoculations was conducted on guinea-pigs, with the following results:

The cultures used were second and third generations obtained in pure cultures from original by transplantations on Löffler's blood serum. The guinea-pigs were all about same size, varying slightly from 400 grammes. (1) One pig, inoculated with half a cubic centimetre of

a twenty-four-hour bouillon culture pure anthrax, died in less than forty-eight hours. At autopsy, pure cultures of anthrax recovered from heart's blood and spleen. (2) Two pigs inoculated on same day as the first, each with half a cubic centimetre of a twenty-four-hour bouillon culture of anthrax and half a cubic centimetre of a twenty-four-hour bouillon culture of the staphylococcus citreus, were alive and well after two weeks, and were subsequently used for other inoculations. (3) One pig, inoculated with one cubic centimetre of twenty-four-hour bouillon culture of the pure citreus failed to produce any marked effect. Animal was kept under observation for a month, and after the first day or two was as lively as ever. The inoculations were all made in the abdominal subcutaneous tissues.

The writer was unable to find any evidence that this action of the staphylococcus citreus was observed before. Other observers have shown that the streptococcus and the staphylococcus aureus possess the same power of antagonizing the anthrax bacillus. Emmerich⁴ in 1886, experimenting on rabbits, found that the streptococcus, injected subcutaneously or into the vein, would arrest the growth of anthrax. He first inoculated the animal with pure anthrax, then followed it with a subcutaneous or intravenous injection of the streptococcus. Other observers have reported a similar action by the staphylococcus aureus and by the capsule bacillus of Friedländer.

POST-MORTEM INFECTIONS.

It is interesting to note the experience of pathological staff with infections from post-mortem work. The only infections worthy of mention have occurred either by hang-nails or by means of hair follicles. By far the greater number occurred through hair follicles. Cuts received by the autopsy knife healed readily. The usual treatment was: allow the wound to bleed freely, wash with corrosive, and dress with corrosive pad. The usual places of hair follicles infection are back of hand and ulnar side of wrist or lower forearm on its posterior aspect. The organisms are massaged into the hair follicles by the friction attending the removal of the various organs, and often by the habit of the operator resting his wrist upon the edges of the open thoracic or abdominal cavities.

In connection with these infections it is also interesting to note that different individuals are more susceptible to certain bacteria than others. For example, in one man connected with the Pathological Department the infections are always with the aureus, while the streptococcus is the infecting organism in another. The writer's experience in four post-mortem infections has been in each case with the aureus.

CONCLUSION.

The writer is indebted to Dr. Thomas B. Cooley, house-physician, for valuable assistance in the work on Out-patient Department cases, and to Dr. Charles S. Wright, aural house-physician, for assistance in taking cultures and preparing report of aural cases.

Medical Visitor to Hospital. — Who in the world is that bellowing and moaning so in the private room?

Assistant Superintendent. — Oh, that is Dr. Ganzewick, our senior visiting surgeon; he had a small furuncle on the back of his neck opened yesterday.

PSEUDO-METALLIC INCRUSTATION OF THE CORNEA.

BY HASKET DERBY, M.D.

I TAKE this title from that which heads an article in the *Revue Générale d'Ophthalmologie*¹ to which Dr. W. J. Daly has called my attention as bearing on a case, the subject of this paper, and which I exhibited to the New England Ophthalmological Society at its meeting in November, 1896.

In the article referred to an account is given of a case brought before the Paris Ophthalmological Society in June, 1896, by M. Darier. The patient, a man, had the previous month got a particle of the horn of some animal in his left eye. A slight corneal ulceration followed, which was treated by iodoform ointment. The patient asseverated that he had never used any preparation of lead, and that this had been his only treatment. When M. Darier saw the man he discovered an erosion of the lower half of the cornea, which presented precisely the metallic white appearance that would proceed from the employment of a collyrium of subacetate of lead. The epithelium had re-formed, but there was ciliary redness and iritis. Since it had been under observation the spot had grown no larger.

In the discussion which followed the presentation of this case, opinions as to its nature were found to differ. Some supposed it to be a calcareous keratitis, others that it was due to infection. The subsequent progress of the disease is not given.

My own case is as follows. Miss X, aged eighteen, was sent me by her family physician December 7, 1895. She had never had any trouble with her eyes until six weeks previously, when, without apparent cause, soon after retiring for the night, a sensation as of a foreign body came on in the left eye and lasted all night. It was unattended by pain, but there was, as she expressed it, a feeling of something "going round" in the eye, and this lasted till morning. The next day the lids were swollen, but the eyeball apparently not affected. October 27th she consulted her physician, who wrote: "She seemed to be suffering from a simple conjunctivitis of both eyes. I examined them with a lens, but could discover no trace of ulceration of cornea. So I gave her a simple collyrium of zinc sulphate and belladonna. Two days later she called again. The eyes were better, but I thought it would be better to strengthen the solution, so made it two grains to the ounce, and I did not see her again till she called on me the day before I advised her to come to you." Four days after the date of this letter the patient suddenly noticed the white corneal spot which is about to be described.

The left eye presented no signs of irritation or inflammation. Situated at the junction of the middle and lower thirds of the cornea was an opacity which covered the lower third of the pupil, at medium dilatation. It was four-sided, nearly rectangular, eight millimetres in length and four in width, absolutely dense, of chalky whiteness, resembling a thin scale of porcelain let into the corneal substance, its edge sharply defined against the surrounding transparent portion. The corneal epithelium seemed continuous over its face. Cocaine having been instilled, the point of a broad needle was passed over the whole extent

⁴ Emmerich, R.: Die Heilung des Milzbrandes durch Erysipelserum, Munch. med. Woch., 1894, Nos. 28-31.

¹ July 31, 1896, p. 300.

of the leucoma, but it slid over its surface and no portion could be detached.

Unable to account for this appearance, save on the supposition that it was due to a deposit of lead, I wrote to her physician and received from him the positive assurance that nothing but zinc sulphate had ever been used as a collyrium.

Different forms of mercurial salve were applied almost daily till the following July. No change having occurred, I sought to excite moderate irritation by the instillation of Sydenham's laudanum. I also suggested tattooing, as a cosmetic measure, in case there should be no change by fall. In November I exhibited the case to the Society, and an opinion was expressed that the leucoma must proceed from the deposit of some preparation of lead. Having observed that the surface of the leucoma had, with time, grown perceptibly rougher, I soon afterwards placed the eye under cocaine, and succeeded in detaching one or two small flakes from the edge of the opacity. I now proposed to attempt removal of the whole, and early in January of the present year she signified her willingness to have the experiment tried. Cocaine was instilled and, after picking a little at the edges of the leucoma, with the point of a broad needle, the entire structure perceptibly loosened and was removed by the aid of a pair of ciliar forceps. It came away in two pieces, which were carefully preserved.

The cornea beneath was rough and the seat of a grayish infiltration. For several days there was swelling of the lids, lachrymation, pain and increased opacity. Gradually these symptoms subsided and the patient returned home. A letter from her under date of February 21, 1897, states that the eye continues to grow stronger, and that there is scarcely a trace of corneal opacity remaining.

Dr. J. B. Ogden, of the Harvard Medical School, to whom the specimen was given for examination as to the presence of lead, writes that he did not find the slightest trace of this metal. He says, "Although the particles were very small, yet if they had contained any appreciable amount of lead it would have been detected in the test which I used."

The entire specimen was consumed in this investigation, and unfortunately no microscopic examination could be made. In fact we had so definitely made up our minds that the patient had, in some way or other got hold of some preparation of lead, and that the specimen would disclose this fact, that this point seemed the chief end of the investigation.

THE CURE OF HERNIA.¹

BY HENRY O. MARCY, A.M., M.D., LL.D., BOSTON.

AMONG the many wonderful achievements in the art of surgery of the present generation, the easy and safe cure of hernia may well command high rank. It is very probable that no one of the many problems constantly pressed upon the attention of the surgeon, because of the multitude of sufferers from this affection, received more careful consideration and profound research by the great masters of the past generation. The special student is astonished at the enormous volume of the literature upon this subject. Over eighty

of the closely printed quarto pages of the index of our great national medical library are occupied by an abbreviated list of titles alone of authors who have written upon the subject of hernia.

It is questionable if the physician of to-day is more familiar with the anatomy, both normal and pathologic, of hernia than was the student in a former generation. It is certainly true, notwithstanding the careful dissections made for, and often by each medical student before graduation, that we are obliged to refer to the noteworthy works of Camper, Cooper, Scarpa, Cloquet, Langenbeck, Bourguery, and others of an earlier period for our most accurate and exhaustive illustrative teaching upon this subject. Indeed, in the earlier period operations undertaken for the cure of hernia were not infrequent and often were successful.

The key, however, was wanting to unlock the mystery which ever invested the surgical problems, and which gave to the repair processes of wounds the ever-illusive complication of the so-called supervening inflammations. The changes ensuing in incised wounds, made for the proper manipulations of the parts involved in hernia were followed by such a high mortality that experience forbade their continuance, and a quarter of a century ago the methods undertaken for the cure of hernia were limited to pressure processes, injections, and the subcutaneous appliance of wire ligatures; and these, in the hands of the most expert, as a rule, failed to cure.

Profiting by the demonstration that the so-called inflammatory processes supervening in wounds were due to bacteriological infection, and that science rendered it possible for the surgeon to make and maintain aseptic wounds as the decided rule in practice, later it became possible to deal with the various structures which are so deformed as to cause a weakness in the retaining abdominal walls.

This accomplished, the problem was simplified to the reconstruction of the parts after their normal pattern, and this pertains to every variety of hernia. However, in order to do this, one more factor in the surgical problems needed solving, and this appeared to me as plainly evident in 1870 as at the present. As I then thought, profiting from Mr. Lister's personal instructions and marvellous demonstrations, that I had mastered the art of making and maintaining a wound aseptic, it seemed a logical deduction, if primary repair ensued after the constricting of an artery by an animal ligature, the same result would follow the coaptation of the tissues by animal sutures.

It is not my purpose this evening, however interesting and instructive the subject may be, to refer to the evolution of these processes which, little by little, became applicable in the rejoining of all aseptic vitalized structures, and which are in daily practice in every surgical clinic.

It only suffices to say that certain precautionary measures are necessary which must pertain to the closure of all wounds:

- (1) That the structures are aseptic.
- (2) That they are devitalized as little as possible.
- (3) That they are coaptated or rejoined by the use of aseptic absorbable sutures.
- (4) That these should be applied so as to hold at rest like structures with the minimum of constriction. This is essential, in order that the vascularization of the parts included shall be diminished as little as possible.

¹ Address before the Surgical Section of the Suffolk District Medical Society, January, 1897. Illustrated by the stereopticon.

(5) The coaptated structures must lie in easy juxtaposition so as to minimize the possible spaces for the formation of blood-clots, and as little suture material is to be used as will accomplish this purpose, remembering that every superfluous stitch inflicts a damage to the structures which must be repaired and adds suture material which must be absorbed. Undue constriction will frequently cause necrosis of aseptic tissues, which contributes by so much to the possible overburdening of the vital processes. The fatty tissues are the least well vitalized and not seldom break down and cause serious trouble even in aseptic wounds. This is especially true in the thick fatty layers of the abdominal wall.

(6) The skin is to be closed by a fine animal suture applied through the deeper layer only so as to coaptate in even juxtaposition its edges, the suture itself remaining buried. When a wound is thus properly closed in layers, there is nothing to drain, its coaptation is perfect, and no foreign material is subsequently to be removed from the parts involved. Hence drainage is not required, and the important end is thereby attained which renders possible to cover the infracted surfaces by a germ-proof seal. This has its ideal accomplishment by the application of a layer of iodoform contractile collodion reinforced by a few fibres of absorbent cotton. The seal should extend sufficiently broadly to hold firmly at rest the evenly approximated edges of the skin. Thus treated, if the wound is *aseptic*, it will remain *aseptic* and *primary union* will supervene. In no part of the body is this more important than in the region of the groin, confessedly one of the most difficult to maintain aseptic under the still too common treatment with drainage and sterilized dressings.

In order to effect the cure of hernia in any part of the body, it is only necessary to become master of these principles and reduce them to accurate, working practice. The former is the *science*, the latter the *art* of surgery. Here we enter a most earnest plea for a thorough familiarity with anatomy and a training in the practice of the art, best acquired under definite personal instruction of a master. The pressing want of to-day is apprenticeship, recognized in the trades, nowhere so important, however, as in the art of surgery. Technique can never be obtained from books.

A brief analysis of the varieties of hernia will necessarily extend beyond the limit of the present occasion, even when treated in abstract, because of the vast extent of the subject.

The simplest form of hernia is perhaps the *Ventral* variety, so commonly met with after laparotomy. Here the dissection must be sufficiently ample to permit the restoration of the sundered structures in co-ordination. If a considerable peritoneal pouch is found, this may be freely resected and the peritoneum evenly held in coaptation by a line of double continuous tendon sutures. The linea alba must be refreshed, and rejoined in a similar way. The skin is closed and the wound sealed as already described. No abdominal belt or bandage is afterward advised. In a personal experience of nearly, or quite, one thousand laparotomies thus closed, the wounds have remained firm, and hernia has occurred in less than one per cent. of the cases.

Inguinal hernia in the female requires no special description, since to this the principles above mentioned pertain.

Umbilical hernia is more difficult. Here the intra-abdominal pressure is usually much greater, the abdominal wall flat, and the contents of hernial sac are often adherent. Not seldom considerable portions of diseased omentum must be dissected and evenly sutured at its base and excised. The abdominal wall can generally be separated laterally in order to increase greatly the coaptating surfaces and secure a more firm union of the strong, unyielding parietal structures.

Femoral hernia requires a careful dissection, guided by accurate anatomical knowledge. If the sac is large, it is sutured and resected. If small and easily reducible, it is good practice to let it alone. Strong structures are slightly refreshed and evenly coaptated by a double continuous suture, closing the opening well in upon the femoral vein. The second layer of sutures coaptates the thick fascia over the plexus of vessels. In whatever way the sutures are introduced, the sheath of the femoral vessels must be brought clearly into view and is best protected by the finger during the suturing. It is surprising to note how little discomfort follows this operation. The results are most satisfactory. So far as I have been able to learn in not a single one of my entire series of cases of femoral hernia has recurrence taken place.

Inguinal hernia in the male.—Only in this variety of hernia, by far the most common and confessedly the most difficult of cure, is there much room left for difference of opinion. By general consensus, the operative wound should be ample to permit of free inspection and easy manipulation of the parts involved. The hernial sac, if at all large, should be opened, its contents inspected and cared for, the sac dissected to its very base, sutured in its long axis and resected. The cord is to be lifted from its bed with a minimum of injury, when it will be noted that in by far the majority of cases, the hernial opening has been caused primarily by an enlargement from above downward of the internal inguinal ring. The structures entering into its composition are relaxed and bulging, and the strong transversalis fascia which makes up the posterior border of the inguinal canal was of primary defective development. It is, indeed, very probable that the larger number of inguinal hernia that occur even late in life are owing to a defective congenital development. By some means the posterior border of the canal must be reconstructed and the canal itself restored to its normal obliquity. This means not so much the transplantation of the cord to new relationships, conditions which have been doubtless recently greatly over-emphasized, as the deflecting of the intra-abdominal pressure so as to bring it at, or near a right angle with the line of the cord, instead of on a line with it. Any method which will accomplish this and permit of primary union will result in the cure of the hernia. The anatomical factorage to be emphasized is the coaptation of the posterior border of Poupart's ligament to the posterior border of the conjoined tendon quite as high up as is necessary to re-form carefully the internal inguinal ring. These structures are coaptated about the cord at its exit from the abdominal cavity. It will be noted that the relaxed transversalis fascia is intrafolded, thereby re-enforcing the posterior border of the canal. The cord is now carefully replaced, and the external sundered structures are rejoined over it. I would emphasize the importance of this procedure, since by so doing a firm strong envel-

ope covers the cord, and the external ring is reformed entirely as in the normal construction of the parts. The advantage of this is apparent in that it protects the abdominal wall from the formation of a direct hernia at the site of the internal inguinal ring.

In this and the character and method of suturing consists the chief differences between the operation called after my name which I have so long advocated and the various modifications, known as the Bassini, Halsted, Fowler, and other methods.

When all the aponeurotic structures, which go to make up the walls of the inguinal canal, are sutured *beneath* the cord, the transplantation of it has been by a direct opening through the strong abdominal wall, and the new canal or bed of the cord is found entirely in the fatty subcutaneous tissues. Even when the nutrition of the testicle does not suffer by this violent transplantation, a new danger is added in the subsequent risk of a direct hernia, occurring through a small opening which must necessarily remain in the abdominal wall.

This is ever in direct line of the intra-abdominal pressure and will be found liable to yield to it in the subsequent history of the patient.

In evidence that this is not an hypothetical criticism is adduced the fact that within a year I have myself operated upon four cases of recurrent direct hernia, following operation by this method.

The plain corollary to the problem is that the surgeon should follow strictly the teachings of normal anatomy and reconstruct the structures as far as possible after the primal order of normal development.

This occasion demands a brevity which permits the criticism of dogmatism. At the risk of emphasizing it, I trust I may be permitted to state briefly that my experience extending over a quarter of a century seems ample to corroborate the statements herein made. In a series now numbering nearly four hundred cases, where the operation has been undertaken for cure, I have yet to see a case where the life of the patient seemed endangered when the integrity of the intestine was not involved. I have operated at all ages from two months to eighty-three years, involving perhaps every variety of hernia. So far as I have been able to trace results, more than ninety per cent. of the cases have remained permanently cured. As a rule, the patient is permitted to leave the bed at the end of the third or fourth week, resuming light duties at the end of the sixth week. No supporting bandages of any character are advised.

My first cases operated upon for the cure of hernia by complete primary closure of the wound by the use of buried catgut sutures occurred in 1870, and were published in the *Boston Medical and Surgical Journal* the following year.

Soon after I instituted a long series of original investigations upon animals in order to determine the exact results which supervened in wounds thus closed. It was clearly demonstrated that an aseptic animal suture was first inclosed by leucocytes which, little by little, invaded its structure with a resulting formation of a living band of connective tissue, replacing the foreign material.

Based upon these demonstrations I readily determined the great importance and value of buried aseptic sutures in all aseptic wounds, nowhere more apparent, however, than in their application for the cure of inguinal hernia.

These demonstrations I made public by a series of articles upon the subject, and it was not until after the acceptance of these teachings, that it became possible to formulate or put into practice any of the modifications of procedure, which have been advocated under various names for the cure of hernia.

The great practical difficulty has been in securing suture material of aseptic, trustworthy character which would maintain its integrity sufficiently long to hold in coaptation the sutured parts, finally disappear by absorption, and leave in its place a vitalized band of connective tissue. For this purpose catgut, no matter how prepared (primarily a flat band of obliquely interlaced connective tissue), is necessarily defective. The tendons of various animals are far more satisfactory. Carefully selected tendons from the tail of the kangaroo furnish sutures of nearly ideal perfection.

Dr. W. Coley, of New York, writes me, under recent date, that he has operated upon three hundred and fifty cases, using kangaroo-tendon sutures, with only one death and but two or three relapses.

It is needless to emphasize here the importance of modern aseptic technique, since upon this the safety depends as well as in large degree the results to be obtained. Present experience, however, is ample to prove that the operation for the cure of hernia in the male, the most difficult of all the forms of hernia because of the complication of the cord, is really not dangerous or difficult, if the principles above mentioned and the anatomy of the parts are well mastered, and the operation for the cure of hernia in a very large proportion of all the sufferers of this distressing and dangerous affliction merits general adoption.

ACUTE PERICARDITIS: A STUDY OF ONE HUNDRED CASES.¹

BY GEORGE G. SEARS, M.D., BOSTON.

THE cases forming the subject of this paper include all which could be found in the general index of the hospital between the 14th of January, 1882, and the 12th of April, 1896, irrespective of whether the pericarditis was the primary affection or occurred as a complication of some other disease. Classified according to the products of the inflammation, 54 were dry, or at least the effusion was insufficient to give distinctive physical signs, 41 were serous, 4 being hemorrhagic in character, and 5 were purulent. Seventy-four were males and 26 females. While no age was exempt, the youngest patient being nine and the oldest seventy-eight years old, the largest proportion was found in early adult life, 42 occurring between the twentieth and thirtieth years. From this as a maximum, the curve quite rapidly and uniformly descended on either side; thus, from thirty to thirty-four years there were 13 cases, and from fifteen to nineteen, 12; from thirty-five to thirty-nine, 8, and from ten to fourteen, 7. Above the age of forty the liability appears to rapidly diminish, 8 only being found in the fourth decade, while but 7 were over fifty. In 2 the age was not stated. No inference can be drawn from the fact that but one patient was under ten as to the relative prevalence of pericardial inflammation among children, since they form a very small part of the hospital clinic. Although the occupation of the patients has

¹ This paper will appear in the Boston City Hospital Medical and Surgical Reports, Eighth Series.

been classed among the general factors which induce the development of this affection, it seems to have exerted but little influence here, as no marked preponderance was engaged in pursuits necessitating any special exposure. The influence of season, however, was more marked, as was to be expected, from the large proportion which were secondary to rheumatism and acute diseases of the lungs, very few being admitted during the four months from August to November inclusive. Among the remaining months the cases were very evenly distributed, although a slightly larger number was found in January. A history of the abuse of alcohol was, perhaps, no more prominent than was to be expected among a hundred hospital patients, no matter what their disease, 23 having used it to excess, while 11 confessed to a moderate indulgence.

A striking feature of these cases was the large percentage in which the heart was already affected, 34 showing evidence of some valvular lesion, either mitral, aortic, or both, while in several others degenerative changes in the myocardium were present. This may have been simply a coincidence, but the number is so large that it is more probable that the pre-existent lesions acted as a determining cause. Besides this frequent association with old cardiac trouble so many of the cases were complicated by, or secondary to, pneumonia, pleurisy, or both, either by direct extension from one to the other, or from a simultaneous infection, that it is difficult, often even impossible, to differentiate the symptoms due solely to the pericardial inflammation, so that but few points in their clinical history are worth noting. Pain was fairly constant, being present in 65 cases, and when absent its place was frequently taken by a sense of oppression in the chest. Its usual position, as was to be expected, was in the precordia or in the left side of the thorax, but in one it was situated only in the back between the scapulæ. Often, however, it was not definitely located, the patients complaining simply of "pain across the chest." Next in frequency was dyspnea, though for reasons which have been mentioned, but little stress can be laid upon it. Palpitation and digestive disturbances were comparatively rare. In a dozen or more instances delirium is recorded, at times so active that the patients required restraint, but these cases were so often complicated by other pathological conditions or by alcoholism that figures are valueless. The febrile movement was almost always slight, although occasionally rising to 102.5° or 103° F. for a single observation. If it exceeded the former figure for several days, even in the rheumatic cases some other acute process, usually pneumonia or pleurisy, was almost always present. Subnormal temperatures continuing for several days, and with wide daily fluctuations, were not uncommon, even when recovery followed. In one very pretty chart what appeared at first glance to be a well-marked septic rise and fall proved to be the variation between a morning temperature of 96° and an evening one of 99.5°. The highest point was reached in a rheumatic case, complicated by pneumonia, 107.4° being recorded just before death.

Recurrent pericarditis occurred in one case of rheumatic origin without any return of the articular symptoms, the relapses, of which there were several, being confined to the pericardium, but running a course perfectly analogous to those which take place so frequently in acute rheumatism where the disease affects only the joints.

From the point of view of diagnosis two cases may be mentioned as showing the necessity of a careful examination of the back as well as the front of the chest, where the possibility of pericardial inflammation is suspected. In one the friction rub was heard very feebly over the precordia, but was pronounced inside, and just above the angle of the left scapula behind; in the other a collection of pus which distended the posterior portion of the pericardium to the size of two fists, its anterior surfaces being glued together by a previous affection, defied detection, and was first discovered at the autopsy. In the former a slight diminution of the friction sound might have rendered it quite inaudible in the usual position although distinctly perceptible behind, while in cases similar to the latter, when the lungs are clear, careful percussion of the back might show an area of dulness whose position might be of great value in diagnosis.

Etiologically, acute rheumatism occupied the most prominent position, as it was associated with 51 cases and appeared in the previous history of four others. Pneumonia or infection with the pneumococcus was next with 18. In seven instances chronic nephritis was the primary disease and in five pleurisy. Chronic rheumatism and gonorrhea are both credited with two cases, while one occurred in each of the following diseases: empyema, tonsillar abscess, acute nephritis, hepatic cirrhosis, and chronic fibrous pneumonia. The latter was apparently not tubercular, but no histological examination was made. Phthisis was, however, present in two others, one of which was also complicated by empyema, but in both the autopsy proved that the pericardial inflammation was of pneumonic origin, and not the result of infection with the tubercle bacillus. The latter may have been a factor in the five cases associated with pleurisy, but in four there was no direct evidence; in the fifth the jagged temperature curve, which persisted as long as the patient was under observation, and the aspiration of bloody fluid from the pericardial sac were strongly in favor of such a possibility, but the diagnosis could only be made by inference. Chorea appeared in the history of three cases, but in only one (a rheumatic patient) was it associated with the pericarditis, and there it came on several days after the onset of the latter.

The nine remaining cases have been classed as idiopathic, no efficient cause being found, although a history of exposure was given in two or three instances, but in only one was the patient in normal condition before the attack. Six had chronic valvular lesions, the result in one case of five attacks of rheumatism, the last five months before, and in another of an attack four years before. In both the latter a rheumatic origin is possible, the infection either being confined to the pericardium, or else the joint symptoms were so slight as not to be thought worthy of mention by the patient. Another case had markedly atheromatous arteries, a somewhat enlarged heart, and, probably, a mitral leakage, while still another was admitted with a soft systolic murmur at the apex, which persisted during his stay in the hospital, but it remained doubtful whether this was the result of organic or inorganic causes.

Many of the cases occurred before cultures were taken as a routine part of an autopsy, but records of a bacteriological examination were found in eight, in four of which pneumococci were found in the pericardial effusion, and in one (acute nephritis) the colon

bacillus. In a third (chronic fibrous pneumonia) streptococci were demonstrated, and, probably, also pneumococci and the Klebs-Löffler bacillus, but the latter were not absolutely differentiated. In one case pneumococci had been shown in the sputum, but the organ at the autopsy proved sterile. In another (rheumatism with recovery) colon bacilli were found in aspirated pleural fluid, but no opportunity was afforded to investigate the contents of the pericardium.

Rheumatism occupies so conspicuous a position among these cases, more than half being attributable to it, that a more detailed account of them is given. Thirty-eight were males and 13 females. The youngest patient was a boy of nine the oldest a man of fifty-two. Only four were over thirty-five and only five under fifteen, but for reasons which have been given the latter figures are no criterion of its frequency in childhood. Between these limits, fifteen and thirty-five, if divided into periods of five years, the cases were very evenly distributed, although a slightly larger proportion occurred between twenty and twenty-five than at any other time. So many of them entered with the signs of pericarditis already present that it is impossible to more than approximate the date of its onset in any considerable number. In a few it antedated the appearance of the joint symptoms, in a few others, they came on simultaneously, but in a great majority it showed itself within the first 15 days. After that time its development was quite rare, yet in one case the first evidence was found on the 34th day. It was decidedly more common in the first attack than in the second and in the second than in the third, the figures being 23, 15 and 7 respectively. After the third attack it was much less common, but in one case it came on as late as the ninth or tenth. It does not, however, necessarily follow from this that the liability successively diminishes, since more patients are admitted in the first or second than in later attacks, and no attempt was made to get at the relative proportion in each. It was also decidedly more frequent where the disease affected many joints, five or more being concerned in four-fifths (41) of the cases, and inferentially also, although the records are not always explicit, when the inflammation was migratory and skipped about from one position to another. Yet it also occurred where the articular symptoms were so slight that the patient complained only of transitory pain, more often in the knees, elbows or shoulders. The probability that the infection was particularly virulent is also suggested by the presence of pulmonary complications in nearly one-half of the cases (23), pleurisy being found in 18 and pneumonia in three, while pneumonia (once on the right and once on the left side and double pleurisy occurred simultaneously in two. Infection by contact appears to have been the usual course, as in the cases of pleurisy the left side was more frequently affected than the right, in the proportion of 12 to 1, while five were double. Of the three simple cases of pneumonia two occurred on the left side and one was double. In cases also where pleurisy was the primary disease pericarditis was more common when the left side was affected, in the proportion of 3 to 1, the fifth case being double; but with the primary pneumonias the condition was reversed, eight occurring on the right to four on the left side, three being double.

But little opportunity was furnished by these cases

of observing whether thorough treatment by the salicylates has any effect in preventing the development of pericarditis, as in nearly every instance it was either present at the time of entrance or appeared only a few hours later, or else the joint symptoms had so far subsided that the drug was not given. Only six patients had obtained an amount sufficient to bring them at all under its influence before the friction rub was discovered, and one of these received but three doses of fifteen grains of the soda salt. The other five received an amount which varied from ten grains every hour for two days as a maximum to fifteen grains three times daily for three days as a minimum. All that can be said is that so far as is known, since it is impossible to tell how much they may have received before admission, the great majority of the cases were not under its influence, but that in a small number it was unable, in the doses given, to prevent its development.

Based on the total number of 100 cases, the prognosis of pericarditis must be considered grave, as 43 per cent. died and four were discharged unrelieved; but when it is considered how frequently it occurred as a complication of some other disorder this estimate of its gravity must be shaded somewhat, according to the diseases of which it formed a part. When associated with hepatic cirrhosis or nephritis either acute or chronic every case but two terminated fatally, and of these exceptions one was discharged unrelieved, while the other was evidently not connected with the nephritis but was of rheumatic origin and went on to recovery after the manner of such cases. Nor is the fatal ending always to be attributed solely to the pericarditis, since its onset is often but one form of expression of the critical condition of the patient, or at most may have hastened the end by adding another item to the load which he was already carrying. So far as these figures go a similar observation is applicable to cases associated with other chronic diseases, all those complicating phthisis, fibrous pneumonia and chronic rheumatism being fatal with one exception, a case of chronic rheumatism discharged unrelieved. Where, however, the primary disease was of an acute infectious nature the results were somewhat better, yet the mortality rate was still very high except in rheumatism. Fifteen out of the 18 cases classed as pneumonia, for example, died, but this undoubtedly over-estimates the true rate, since several fatal cases are included in this list which would have been overlooked had not an autopsy been held, as the pericardial affection had not manifested itself by any physical signs, an occurrence probably not uncommon in pneumonia, whatever the outcome, its signs and symptoms masking those of the secondary disease. Both cases complicating gonorrhea, two out of the five cases of pleurisy (another was discharged unrelieved), and the single case of empyema, were all fatal. The case complicating tonsillar abscess recovered. The marked contrast in the result between those cases which were secondary to acute rheumatism and those which complicated all other affections is shown by the following figures. 10 only of the former dying out of 51, while 32 out of 40 of the former were fatal, and three were discharged unrelieved.

Of the 10 rheumatic deaths, two had pneumonia, three pleurisy, one of whom was also suffering from old valvular disease, and one had pneumonia, serous pleurisy and old endocarditis. Two others had advanced

cardiac lesions and another died of delirium tremens. The tenth entered moribund, and a satisfactory examination was impossible, but the presence of a pericardial effusion was demonstrated by a post-mortem aspiration of the sac.

Of the nine so-called idiopathic cases but one died, and he was also suffering from a chronic valvular lesion. Another with the same complication was discharged "unrelieved," a term which applied more to the valvular than the pericardial affection, the signs of which were fast subsiding.

In view of these results it seems justifiable to say that in itself acute pericarditis is not a very serious affection, but when it comes on in the course of some chronic disease, or when the integrity of the heart has been already invaded by previous valvular lesions, when pneumonia or pleurisy are also present either as the primary disorder or as coincident complications, or when it is due to a general septicemic process, as in the gonorrheal cases, the outlook is serious.

The medical treatment given may be dismissed in a few words, as it was entirely symptomatic, save that in some instances an ice-bag, more rarely a poultice, and still more rarely a blister, was applied to the precordium. The subject of paracentesis, however, deserves fuller discussion, although I have been unable to find any mention of its being attempted in more than four of the 46 cases where effusion could be suspected from the physical signs. In a large number of them it was so slight that the question of aspiration evidently did not arise, in others the prompt absorption of the fluid confirmed the wisdom of the policy of non-interference, but in a few of the fatal cases no explicit explanation could be found in the records of why it was not done, although probably, as most of them were complications of some serious process, it was thought that the critical state of the patient was due to other conditions than the presence of fluid, and that puncture would add to his discomfort without hope of granting him any relief. The necessity for puncture may be stated in general terms to arise when the action of the heart becomes embarrassed by the amount of the effusion, but a consideration of these cases also shows that the time must vary somewhat according to the disease with which the pericarditis is associated. In acute rheumatism, for example, the tendency toward recovery, even when the effusion is very large, is so strong that in most instances nature may be allowed to take its course, whereas in others a prompt resort to aspiration is imperative. This would seem to be notably true of pneumonia from the possibility that the fluid may be purulent, four of the five cases where the effusion was of this character being found in connection with that disease, while the fifth occurred as a complication of empyema, which may have been due to the same cause. The disappointing results which have so frequently followed permanent drainage of the pericardial sac might at times be averted if the diagnosis had been made promptly before the heart had become weakened by the continued presence of the fluid. That the danger arising from wounding the heart is theoretical rather than real received another illustration in one of these cases, when the needle thrust into the sixth interspace just to the right of the sternum entered a "solid body which pulsated" and caused it to describe an arc of one and a quarter inches with each beat; no harm resulted. Of the three other cases the site selected was in one in the

fifth interspace on the right, and in another in the fifth just to the left of the sternum. In the third fluid was obtained in the same interspace on the left just inside the nipple line; while an attempt with a hypodermic needle in the fifth right space failed; another attempt made later in the fourth left space slightly inside the mammillary line was successful.

Clinical Department.

FOUR CASES ILLUSTRATING A MARKED DEPARTURE FROM THE USUAL PHYSICAL SIGNS OF PLEURITIC EFFUSION.¹

BY VINCENT Y. BOWDITCH, M.D., BOSTON.

My object in reporting the four following cases, which occurred in two of my services at the hospital, is to emphasize the fact that frequently the typical signs of a pleuritic effusion, especially that of a diminished respiratory murmur, may be supplanted by the usual sign of consolidation, namely, marked bronchial respiration, a fact which causes at times a good deal of difficulty in diagnosis, to be decided only by the aspirating needle.

That faint bronchial respiration may be heard in the region of pleuritic effusions is doubtless mentioned in some text-books, but I fail to find sufficient allusion made to the not infrequent cases in which the signs are such as are usually taught to the beginner as characteristic of intra-pulmonary rather than pleuritic disease. It is only comparatively recently that I have had cases brought to my notice in which the bronchial breathing mixed with râles has been very marked over the seat of effusion; and from my experience with aspiration in these cases I am led to believe that in one or two others which I can recall where in convalescence from pneumonia days after the return of the temperature to normal the marked bronchial breathing persisted, and which I attributed to an unresolved condition of the lung, there was a pleuritic effusion present, the amount of fluid, however, probably not being very great. In consequence of this experience I should never hesitate to aspirate under the conditions mentioned, believing that less harm can come to the patient by possibly puncturing a solid lung with a sterilized needle than by leaving a pleuritic effusion to partially hamper the free action of the lung.

CASE I (Vol. 401 B, p. 124). A. C., male, thirty-one, single, cigar-maker. Previous history shows nothing of special importance. Entered April 2, 1896.

Personal History.—Bad cough, with malaise, for eight weeks. Gave up work the day before entrance, when he had a chill and a sharp pain in the right breast and shoulder-blade. Considerable expectoration for twenty-four hours; bloody at time of visit.

Physical Examination.—Sputa hemorrhagic. Dyspnea.

Lungs.—Good resonance and respiration over left front and back; slight dullness over right front below fourth rib, and here respiration is faintly bronchial. Dullness in right back from one inch below spine of scapula, becoming flatness below at base, but not extending into axilla; over this area breathing is tubular,

¹ This paper will appear in the Boston City Hospital Medical and Surgical Reports, Eighth Series.

more intense in upper portion; voice sounds are intensified, and tactile fremitus is slightly increased. The apex beat was seen best about in the mammillary line.

April 6th. Dulness, amounting almost to flatness, over entire right front and back with tubular respiration; a few crepitant and medium moist râles over back and front. From this time on for several days, bronchial respiration, numerous crepitant râles, and medium moist râles were heard all over the right back, and signs of an extension of a pneumonic process into the left lung were also present.

The temperature came down to normal by lysis.

April 25th. There was slight dulness in the right apex in front and all over the right back compared with the left. Respiration remained bronchial in the right back, but indistinct in the axillary region.

Previous to this time, from the fact of the persistence of the bronchial respiration, it was thought to be simply a case of unresolved pneumonia, and the possible presence of fluid was not entertained until the persistence of the dulness and a slight lessening of the tactile fremitus in the right axillary region suggested the wisdom of aspirating the chest. May 1st the smallest aspirating needle was inserted just below the angle of the right scapula, and twenty-four ounces of clear yellow serum were withdrawn. The day following showed an entire disappearance of the bronchial breathing, leaving only a diminished respiratory murmur and absence of tactile fremitus.

On May 10th the respiration was again slightly bronchial, but the other physical signs had improved, and he was discharged.

On June 1st he returned for examination, having been in the country for two weeks, and the physical examination showed a good percussion note and respiration throughout the chest.

Synopsis of Case.—Pneumonia of right lung, with the usual signs of that disease. Bronchial breathing persists after fall of temperature and apparent convalescence of patient. Aspiration proves the presence of one and a half pints of clear serum in the area showing bronchial respiration.

CASE II (Vol. 401 B, p. 214). H. N. B., male, twenty-one, single, ward-tender. Entered April 14, 1896. Diphtheria and typhoid fever several years before entrance.

Five days before entrance took cold after nursing several severe cases of pneumonia. Two days later hard cough with tightness across chest. Sputa scanty and whitish.

Physical Examination showed at first nothing but a few moist and sonorous râles scattered about both lungs.

April 22d. Eight days later there was a more marked rise of temperature, much dyspnea, cyanosis, and the general aspect of pneumonia, although the sputa were not rusty, but bloody and slimy. Over one area near the angle of the left scapula bronchial breathing and some crepitant râles were noticed.

May 1st. Ten days later the dulness in left back showed a line of demarcation quite marked about the posterior axillary line. Bronchial breathing, crepitant and numerous coarse, almost bubbling râles, were heard over this region. No dislocation of heart. Sputa dirty, slimy, occasionally bloody.

Four days later the space of dulness increased, although not in a manner to indicate a pleuritic effusion

especially; that is, the line did not rise in the axillary region. In spite of harsh bronchial respiration, however, all over this region aspiration was resorted to just below the angle of the scapula, and 12 ounces of serum, rather brownish and turbid, were withdrawn. After this the physical signs gradually improved up to the time of the patient's discharge.

Examination of the sputa showed an absence of tubercle bacilli, but unfortunately no return was made as to the possible presence of the pneumococcus.

Synopsis of Case.—Typical case of pneumonia. Harsh bronchial respiration persists several days after fall of temperature and marked improvement of general symptoms. Tentative aspiration over site of bronchial breathing resorted to. Withdrawal of twelve ounces of brownish serum. Immediate diminution of bronchial respiration.

CASE III (Vol. 401 B, p. 208). J. J. O'C., fourteen, male. Entered April 14, 1896. Pneumonia three years before entrance, scarlet fever one year before, and, about five weeks before entrance, acute articular rheumatism.

Two weeks before entrance pain about heart with dyspnea; feverish. No rheumatic pain at time of entrance.

Physical Examination.—The percussion and auscultation of the heart showed the presence of a pericarditis with endocardial murmurs also present.

Over the lungs dulness was noticed in the left axillary region and at both bases behind. On the left, the dulness began one inch above the angle of the scapula, over which region the respiration was bronchial and there was whispered bronchophony. Respiration in the right base also faintly bronchial, with the vocal sounds increased. Later this character disappeared, and friction rubs developed in the right lower back, but the dulness and bronchial respiration in the left lower back persisted.

As the line of dulness extended in an upward curve in the lower axillary region, the presence of an effusion, *in spite of the bronchial respiration*, was thought probable, and aspiration one inch below the angle of scapula was tried, and about four ounces of bloody fluid were withdrawn.

Six days later the percussion note was more tympanic in character, and the bronchial respiration was replaced by a lessened murmur.

The patient slowly improved, although the cardiac symptoms persisted, and two months after entrance he was discharged, at which time there was fair resonance over the left back; the respiration was rather harsh, with a few indistinct râles or fine friction sounds after forced inspiration.

Synopsis of Case.—Peri- and endo-carditis with pleuritic effusion in left lower back, proved by aspiration in spite of marked bronchial respiration in that region.

CASE IV (Vol. 362 A, p. 130). A. T., female, twenty, single, laundress at Boston City Hospital. Entered October 2, 1893.

Previous history excellent, except for "brain fever" as a child after exposure to sun. Strong and well since.

Two days previous to entrance felt a sharp stinging pain in the right side near the edge of the ribs, increased upon deep inspiration. No chill, no cough. Headache.

Physical Examination at entrance was negative

throughout. Temperature 102.4°, pulse 88, respiration 24.

For at least seven days nothing new could be discovered upon examination, but almost continual pain in the right flank was complained of. At the end of that time slight cough began to appear, and extreme dullness increasing to flatness in lower right axillary region was noticed, and the same conditions in the back from one inch above angle of right scapula. Over this region was heard faint bronchial breathing in various portions mixed with crepitant râles and in places diminished respiration.

Slight amphoric whisper in different parts of this area. Some râles noticed in axillary region and in lower right front, but not so marked as behind. Respiration in front puerile. Vocal fremitus faint on both sides; rather less on right side. Impossible to find apex beat.

Four days later, although the bronchial respiration, amphoric whisper, and crepitant râles persisted, from the fact that the dullness slowly moved upwards, and there was slight change of note upon change of position on the right side, an exploring needle was inserted about one inch below the angle of the right scapula, and about 29 ounces of reddish fluid were withdrawn.

The note made on that date reads as follows:

"The only definite physical sign of pleuritic effusion as distinguished from a pneumonic process was the change of percussion note upon change of position. There was no apparent dislocation of the heart, no special difference in vocal fremitus while numerous crepitant râles and faint bronchial respiration with amphoric whisper could be heard throughout region of dullness. Three days after operation, the dullness was about the same. The râles had entirely disappeared, the amphoric respiration persisted, and for the first time the heart apex was distinctly felt outside the left mammillary line. One week after the first operation it was repeated, and four ounces of clear serum were withdrawn. The amphoric respiration disappeared after this, leaving only obscure respiration over the point of dullness, which slowly lessened, and the patient was discharged convalescent one month after entrance."

Two examinations of the serum failed to show the presence of tubercle bacilli or other objects of special import.

Synopsis of Case.—No definite physical signs for a week after entrance. Development of dullness in right back diminishing upwards with crepitant râles, bronchial respiration, and slightly amphoric voice over area of dullness. Tentative aspiration proved presence of fluid.

In Cases I and II the general signs of pneumonia were so marked that the diagnosis could be reached almost by the aspect of the patient and by the peculiar soft crackling sound of the respiration, heard without applying the ear to the chest, combined with the short, almost incessant cough so common in pneumonia. The persistence of the bronchial respiration in both of these cases, therefore, as far as the presence of fluid was concerned, was most misleading.

In Case III the whole appearance of the patient was one which suggested tubercular disease, and the bronchial respiration and dullness in the lower left chest suggested the possibility of consolidation rather than an effusion, the presence of which was proved by aspiration.

In Case IV the general symptoms gave no aid to the diagnosis, but the bronchial respiration and the presence of râles more or less disseminated over the affected area, the absence at first of apparent dislocation of the heart, made the diagnosis difficult until aspiration revealed the presence of fluid.

Reports of Societies.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

PAUL THORNDIKE, M.D., SECRETARY.

REGULAR Meeting, Wednesday, January 6, 1897, DR. H. L. BURRELL in the chair.

DR. H. O. MARCY presented the subject of

THE CURE OF INGUINAL HERNIA IN THE MALE.¹

DR. RICHARDSON: I had no idea of making any remarks on this subject. I came for the purpose of hearing what Dr. Marcy had to say, and I have been very much interested in what he says about the use of the tendon suture. I have to do with hernia, as any general surgeon does. I have had a very limited experience with it, and I do not feel that I can say anything of any special value. The method I have used has been that of Halsted, and I am not able to say anything about the ultimate results of my cases, for I have seen almost none of them since the operation, and I have not had occasion to look up the subject. I like to use for buried sutures silk and silver wire. For a long time, when Dr. Mumford was with me, we used silver wire for everything, external wounds and buried suture, and in all the hernias in 1889, 1890, 1891 and 1892. In most of the wounds I closed the structures with deep silver wire. These buried substances are still there; and I have never seen trouble from silk, and do not recall any cases in which it was necessary to remove the wire. I have intended to use the kangaroo-tendon suture of Dr. Marcy, which every one speaks of in the highest terms. I think Dr. Marcy is deserving of very great credit for the work he has done on hernia and for the introduction of this animal tendon.

DR. N. GREENE: I have no statistics to give of the results of the various methods of operating, as I do not have the opportunity to follow out cases. A great many cases come to me to have trusses applied that have been operated upon and the operation has failed; but as, in most of these cases, I do not know the special method employed, I am unable to give an accurate estimate of the value of one operation as compared with another. Occasionally an intelligent patient comes to me who is able to tell what has been done in his case, or the surgeon sending him informs me as to the details of the case, so that I know the special operation that has failed; but I cannot now classify these so as to give information that will be of interest or value to this discussion. I will add, however, that I have not had as many apply to me for trusses, because of the failure of the operation, this year as in previous years. I think advance is constantly being made by the surgeons. They are doing a better, more thorough operation than ever before.

DR. E. W. CUSHING: There is only one point that

¹ See page 381 of the Journal.

has not been brought up this evening, and that is, that if the operation for hernia is a simple and good thing in men in spite of the difficulty of providing for the cord, *a fortiori* it is simpler and better in women who do not have any cord to take care of. I had the advantage of instruction from Dr. Marcy a good many years ago in regard to this method of operating for hernia, and I have made a practice in a large number of women with hernias, who came under my care for operations under ether, to repair the hernia at the same time, and it gives most satisfactory results. And it seems, as Dr. Marcy implies, that people with hernias ought to be repaired rather than be subjected to wearing a truss all their lives. In regard to the suture, I was looking over an old volume representing the work of the sixteenth and seventeenth centuries in repairing hernias, in which I found the use of gold wire was in full operation at that time, although it was usually deemed best to perform castration at the same time. It was generally supposed in this country that Dr. Sims had most to do with the introduction of wire for sutures, but it is a very old method.

DR. GOLDTHWAIT: With reference to the age at which operations may be performed, I should like to report a case which I saw some years ago with Dr. A. S. Knight.

The child had a strangulated inguinal hernia, the bowel having been down for nearly forty-eight hours. An operation was performed and the child made a perfect recovery.

DR. BURRELL: The subject of the radical cure of hernia has always interested me deeply. For the last five years I have been using kangaroo tendon, and have been thoroughly satisfied with the results. Last year I used some moose tendon which I was fortunate enough to secure, and I was very much disappointed in its strength, for it frayed out and was not sufficiently strong.

So far as the indications for operation are concerned, I don't think I can take the position that Dr. Marcy does in reference to this matter. It seems to me, if he will pardon me for saying so, that his position, which as I understand it is advising operation in every hernia, is advanced ground.

I believe that each patient with a hernia should be considered as an individual. If the hernia is untrussable, there can be no question as to the advisability of operating. If, on the other hand, the patient's life will be endangered by operating owing to some coexisting disease, as, for example, chronic interstitial nephritis, it is improper to operate.

It is true that there is extremely little risk in doing the radical cure of hernia, and in skilful hands the results are extremely satisfactory, but there is the danger of an occasional slip-up in antisepsis. If it does occur, we must recognize it. I know that anti-septic surgery is not "cock-sure" surgery, and this is a thing that must be recognized as a fact.

A patient who has a hernia which is untrussable or irreducible, or one which, by the circumstances of his life, is liable to become strangulated, I believe should be strongly advised to have an operation. If, however, a patient has a hernia which is held by a truss, I believe that this patient should have presented to him clearly the advantages to be gained by an operation, and the patient should decide whether he will be operated on or not.

DR. MARCY, in closing the discussion, thanked the

members for their interest evinced in the subject, and said that the decision as to when one should operate must ever be determined by the individual conditions. Surely, the young as a class should be cured. In middle life, all cases where the truss fails to retain the abdominal contents and the general health is not impaired are proper subjects. Age, *per se*, is less an objection to operation than earlier believed. Aseptic wounds do well in elderly people. Dr. Marcy has operated upon thirty individuals over sixty years of age with uniform good results. Often he prefers the cases of large, old, retained hernia, especially when he is desirous of making a demonstration of the technique of the operation to members of the profession.

DR. C. G. CUMSTON read a paper on

TERTIARY SYPHILITIC EPIDIDYMITIS, WITH A REPORT OF A CASE.

DR. MUNRO: I should like to call attention to one particular. I recall seeing four cases during the last year, and three of these came for treatment of hydrocele. The hydrocele had been tapped in each patient two or three times. There was undoubted gumma of the epididymis. In two of the cases the chancres had occurred nine or ten years previously, and one man claimed that he had had the chancre nineteen years ago. In one case the cord was involved as well as the epididymis. I think it is rather important to bear in mind that cases like these apply for treatment of a hydrocele which may be secondary to syphilis of the epididymis. In three of the patients the disease was unilateral, while in the fourth there was a considerable enlargement of one testis without involvement of the epididymis and in the side that had the gumma of the epididymis there was also gumma of the testicle itself.

Recent Literature.

The American Year-Book of Medicine and Surgery.

Being a yearly digest of scientific progress and authoritative opinion in all branches of medicine and surgery, drawn from journals, monographs and text-books, of the leading American and foreign authors and investigators. Collected and arranged, with critical editorial comments by eminent American specialists and teachers, under the general editorial charge of GEORGE M. GOULD, M.D. Profusely illustrated. Philadelphia: W. B. Saunders. 1897.

The issue of this work for 1897 contains 1257 pages, including the index, which is very complete, as it should be in a book of this sort. This is 75 pages more than last year. We have nothing to retract from the comments made upon this Year-book for 1896, and nothing to add except to emphasize the statements there made. The editor is the same, and the editorial staff is, in the main, the same. Dr. Duhring succeeds Dr. Hardaway in the editorship of the Department of Dermatology and Syphilis. The same thoroughness and the same expert intelligence mark the various sections this year as last. The practitioner will not regret the acquisition of this excellent and useful volume.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, APRIL 22, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

ANTISTREPTOCOCCIC SERUM AS A PROPHYLACTIC IN CASES OF OPERATION INVOLVING SUBSEQUENT SEPSIS.

THE difficulty of establishing the proposition that in cases of septic infection which have recovered after injection of antistreptococcic serum, the recovery has been due to the action of the serum, must have presented itself to all who are conversant with such cases, and who have read the published reports. So large a number of cases of streptococcus infection get well under strictly surgical combined with stimulating and supporting treatment, the virulence of infections varies so greatly, and it is often so hard at the beginning of a case to estimate the extent and virulence of the infection, that statistics as to the results of antistreptococcic serum injections are, and will probably remain of little help to us in forming an estimate of the value of this method of treatment.

In cases of septic infection we are not dealing, as in diphtheria, with a definite disease, which enters the system by a single infection atriun, a disease which may be now practically always definitely diagnosed, is reported to boards of health, and with regard to which statistical information of real and definite value may be secured. On the contrary, the course of these cases of streptococcus infection and the rapidity with which irremediable general infection takes place, show such great variation as to greatly impede the formation of a correct judgment of the value of the serum; so that, as Watson Cheyne remarks in a recent number of the *Practitioner*, the proof that the recovery of the patient in the published cases has been due to the injections, is not quite satisfactory. At the same time the experimental evidence is strongly in favor of the view that the serum ought to exercise a prophylactic action, and Cheyne suggests that trial ought to be given to the serum as a prophylactic in cases where unavoidable infection is to be expected, such as operations upon the tongue and throat and about the rectum. It is well known that extensive operations about the

tonsil, pharynx and base of the tongue are frequently fatal by reason of the occurrence of a septic pneumonia due to streptococcus infection. With the idea of, if possible, preventing any such complication, Cheyne has employed the antistreptococcic serum in three cases of this nature.

In the first case, which was one of carcinoma, involving the base of the tongue, the anterior pillar of the fauces and the tonsil, the cervical lymph glands, and necessitating preliminary tracheotomy and ligature of the external carotid, antistreptococcic serum was injected on the two days preceding the operation. There was no elevation of temperature after the first twenty-four hours following the operation, with the exception of a single rise some days later, which Cheyne attributes to the after-effects of the serum. There was no inflammation or tendency to septic infection about the wound, no septic smell in the breath, and the case recovered without any complication whatever. On the day after the operation 10 cubic centimetres of serum were injected and on the fifth day the rise before alluded to, which reached 100°, occurred; it was attended by the appearance of a serum rash over the body, which passed off in a week, and did not affect the patient's general condition.

Cheyne's second case was one of malignant disease of the left side of the lower jaw, spreading onto the inside of the cheek and the anterior pillar of the fauces, and involving the posterior part of the alveolar process of the upper jaw, together with a few cervical lymph glands. Injections of the serum were made on the two days preceding the operation and on the morning of the operation. The case quickly recovered without any trace of septic complication and with no rise of temperature after the first twenty-four hours, when it only reached 100.4°.

The third case was one of very extensive epithelioma of the tongue and floor of the mouth, spreading onto the tonsil and involving a large mass of glands in the neck. The patient was so weak that after the extensive operation for removal of the glands, it was thought best to postpone the excision of the tongue until she had recovered some strength. In all 90 cubic centimetres of the serum were injected, and during the four days following the operation there was the same absence of septic infection. On the fifth day the tongue was removed, and again there was absence of sepsis, and everything looked well, when the patient died suddenly from cerebral embolism. The post-mortem showed that a thrombus had formed in the lingual artery and extended to the external carotid, whence an embolus had been carried to the brain. In this case a little sloughing was found in the posterior part of the wound; but the greater part was clean, and had it not been for the unfortunate accident of thrombosis, Cheyne thinks that the case would undoubtedly have gone on to recovery.

Although the number of these cases is too small to enable us to form any judgment of the value of antistreptococcic serum as a prophylactic, the results

were certainly not such as to discourage others from making a trial of the serum in similar cases. If the septic pneumonia, and diffuse septic infiltrations which so often follow these operations can be prevented, the prospects of success in undertaking them will be greatly increased.

The use of the serum as a prophylactic rather than as a curative agent, will, it is to be hoped, be given further and more extensive trial.

MEDICINE, SORCERY, WITCHCRAFT, SPIRITISM IN THE MIDDLE AGES.

EDMOND DUPOUY has written a very readable book on "Medicine in the Middle Ages"¹ in which he gives much interesting information about monk-lore, the great epidemics, and especially the demonomania of the dark ages. We will follow him through the mazes of this last subject.

Dupouy traces the origin of the occult sciences back to the most remote antiquity. They were a part of the philosophical lore of the Eastern civilizations and were derived from them by the Western nations; genii and demons, good and bad, and the preponderant influence of these agencies on mankind were accepted. After the fall of the Roman Empire, epidemics of demonolatry prevailed for successive centuries, like the pestilential maladies of the sixth, thirteenth and fifteenth centuries. The magic of the Chaldeans and Middle Ages was, according to Dupouy, a form of hypnotism and spiritism. The application to medicine of notions embraced under the heads alchemy, magic, the black art, etc., was a characteristic feature of the pathology and therapeutics of those times when Jean of Valois, Knight-errant, thanked God that he could neither read nor write. Disease was regarded as the infliction of some malignant power, and there was an undeniable potency in enchantments and exorcisms. Gifted minds, like Ambroise Paré and Jean Wier in the sixteenth century, were tinctured with these notions. The familiarity which the writers of that age and previous ages show with such mysterious supernatural agencies as work mischief to man is evidenced by some of the names applied to them by Ambroise Paré "the father of French Surgery": *Cacodemons, coque-mares, incubes, succubes, goblins, lutins, mauvais ange, Satan, Lucifer, etc.*

In 1459 there was an epidemic of demonomania in Arras, a city of Artois, which resulted in the speedy execution of many of the victims, who died confessing the most horrible crimes committed under a solemn pact with Satan. The records of the courts of that age exist, and are full of disgusting particulars a part of which Dupouy, with a keen appreciation of the rank and gross in literature (as evinced in his former work on "Medicine and Manners of Ancient Rome," in which he has massed together all the passages ordinarily expurgated in the Classics), has served up in Court-Latin for the delectation of his Parisian readers. A

similar epidemic prevailed in Valery-en-Savoie in 1574, in which eighty peasants were burned at the stake, and in Haut Languedoc, where four hundred persons perished in the same manner. In 1582, a great many persons were executed at Avignon by the Inquisition for witchcraft. The number subsequently put to death for the same offence is almost incredible. These are matters of common history.

The hystero-demonomania of the cloisters was an epidemic neurosis, characterized by complex disorders of the nervous system in which symptoms of this kind were noted: cutaneous anesthesia (constituting those "marks of the Devil" for which the inquisitors searched with their pointed steel instruments); hyperesthesia and spasms of the stomach and abdominal organs, with hallucinations of poisoning by the victims; hyperesthesia of the uterus, vagina and ovaries, and hallucinations of painful cohabitation with the incubes; spasms of the pharynx and laryngeal muscles manifested in the barkings, cough, cries of the prodromal period of the convulsive attacks; vaso-motor troubles showing themselves in various cutaneous stigmata attributed to the Devil; somnambulisms, aptitude for hypnotic and waking-state suggestion, catalepsy, lethargy, delirium, etc. Charcot, Bourneville and others have made an exhaustive study of these convent epidemics, and shown their affiliation with ordinary hysteria. Among these epidemics were noted the hystero-epilepsy of the nuns of Uvertet, in 1550, the convulsive hysteria of the convents of Sainte Bridgette, of Kintorp, of Nazareth, in 1554, in which Jean Wier "recognized that the *religieuses* were possessed by the demon of lubricity, and that the most frightful debauchery reigned in the monastery." Much has been written concerning the demonolatry of the Ursulines of Loudon, in which were fully illustrated the ignorance concerning diseases of the nervous system of that period, the weakness of character and incompetence of the physicians, and the fanaticism of the monks and clergy. The phenomena of this epidemic were almost exactly reproduced among the nuns of the convent of St. Elizabeth of Louviers, in 1643. They had active hallucinations of all the senses, convulsions and delirium. Like the Ursulines, these unhappy victims blasphemed, vociferated, gave themselves up to all imaginable contortions, declared themselves possessed of devils and described in obscene terms the orgies of the "Sabbath."

The painters and chroniclers of those times have given us representations and descriptions of these epidemics, and of St. Guy's Dance, of the Convulsionists of St. Medard, etc., which are invaluable to him who would study that protean malady, hysteria, in all its phases. The phenomena were conformable to the beliefs and superstitions of the times; in many instances, the malady was intensified by the cruelties and perquisitions of inquisitors and fanatical judges, the dense ignorance, the poverty and misery of the masses. The popular cerebrum was in a state of absolute receptivity to all pathological influences of a nervous

¹ Le Moyen Age Médical, Paris, 1896, Soc. d'Éditions Scientifiques

nature. Children were taught erroneous beliefs and legends. They acquired a vague sentiment of unrest, and a constant preoccupation of sin prevailed. Religious monomania is often linked to intense sexual excitation and erotic ideas. These latter lead to corresponding hallucinations.²

Thus far the ordinary medical reader will follow this author with interest and with sympathy.

A long chapter devoted to "Hysteria and the Psychic Force" seems, in the connection, rather illogical and inconsequential, but serves to bring out the peculiar views of the author as to spiritism. Modern spiritualism, according to him, is really a continuation of medieval demonology. The poor victims of the tribunals really were "possessed" in the literal sense of the term, and so far the judges were *right*. It is the old demonological interpretation revamped: *mutato nomine permanet res*. After conceding the naturalistic explanation (now held by modern neurologists), presto, he returns to the supernatural hypothesis. The demons barred out at the gate, come back by the open windows.

It is somewhat exasperating to find him referring complacently to such self-confessed and often exposed frauds as Slade — now everywhere discredited, to the elder Fox sister who late in life owned to the trickery of her early performances, to the Katie King episode, etc. He speaks of the phenomena of movement without contact of solid bodies as common occurrences, which, he says "I have myself frequently witnessed." Many of his *confrères* at home and abroad would pay very liberally to witness a phenomena of the kind, such as he says, occurs at the séances of Madame L. B. He explains the phenomena of double personality as implying possession by another spirit (page 276) apparently ignorant of the researches in this department of mental physiology by his countrymen Janet, Guignon, Ribot, Richet and others. We might refer him also to the "Proceedings of the Society for Psychical Research" as a warning not to be too rash in forming conclusions.

Dupouy scores the doctors of to-day for their incredulity and scepticism, and because they will not investigate. Many of them have done so and find nothing worthy of investigation; others wait till the spiritualists shall have weeded out the frauds from their ranks.

THE HYGIENE OF SWIMMING-BATHS.¹

In a paper upon the swimming-baths of Berlin, Baginsky makes the following observations:

"(1) The swimming-baths constitute a hygienic arrangement for the population of those large towns which cannot make sufficient use of the river bathing-establishments.

"(2) For this reason the swimming-baths should be

¹ Verhandlungen der Deutschen Gesellschaft für öff. Gesundheitspflege zu Berlin, No. 6, 1896, p. 95.

² Dupouy: *Loc. cit.*, p. 172.

placed under constant sanitary and police control, which should attend to the choice of location, cleanliness, ventilation, clothing-closets, soap-boxes, normal condition or character of the water in use, the quantity flowing in and out, the regularity of the complete cleansing of the tanks, and the daily number of bathers.

"(3) Thorough scientific investigations as to the limits of the use of the bathing water should be made under the charge of the sanitary and police officials."

The foregoing observations appear to have been written in consequence of certain criticisms which had been made as to the management of the swimming-baths of Berlin, six in number. The following are the principal points of interest relative to these baths:

The Neuenburger Street bath or tank, has a size of 12 by 8 metres and a capacity of 160 to 170 cubic metres (42,000 to 45,000 gallons). The number of bathers averages 300 to 400 daily in summer, and 100 in winter.

The Askaniabath has a capacity of about 40,000 gallons.

The Admiral's Garden bath, Friedrich Street, is 15½ by 9 metres, has a capacity of about 63,000 gallons, and is inlaid with glass tiles.

The Commandant Street establishment has one large swimming-tank for men, 26 by 16 metres; one tank for learners, 9.2 by 5.15 metres; one large tank for women, 17.6 by 9 metres; and one small tank for women, of the same size as the small tank for men. The depth of the large tank ranges from one to four metres.

Cleansing-baths are also provided, which must in all cases first be used before the bather enters the swimming-tanks.

Of the two public city baths, one has a capacity of 80,000 gallons, and accommodated 20,014 bathers in the fiscal year 1894-95. The other, with a capacity of 60,000 gallons and a size of 15 by 8.5 metres, accommodated 141,281 bathers in the eleven months ending February, 1896, or an average of 539 in summer and 280 in winter. The water was partly that of the public supply and partly from wells.

The frequency of renewal of the water in the swimming-tanks varied in the different establishments, but was usually daily or every other day in summer, and twice or three times a week in winter.

In this connection it may very properly be stated that the town of Brookline, Mass., was the pioneer town in New England to establish the first municipal, all-the-year-round bathing-establishment, with all the necessary appliances of cleansing-baths, swimming-tanks, etc. Instruction is given in swimming; and a town swimming-club has been organized. The establishment is a model and well worthy of imitation by other municipalities, and it is to be hoped will be appreciated and supported in a way to encourage such imitation.

MEDICAL NOTES.

LORD LISTER'S PORTRAIT PRESENTED TO THE ROYAL COLLEGE OF SURGEONS.—The portrait of Lord Lister, painted by Mr. W. W. Ouless, was presented to the Royal College of Surgeons on March 29th.

SUMMER COURSES IN PATHOLOGY AT THE JEFFERSON MEDICAL COLLEGE.—The Board of Trustees of the Jefferson Medical College have decided to open the laboratories of that institution for summer courses for post-graduate and under-graduate students in histology, pathological anatomy, and bacteriology.

TUBERCULAR APPENDICITIS.—At a recent meeting of the Société de Chirurgie of Paris, M. Letulle said that he had made special researches on the nature of appendicitis, and came to the conclusion that it was in all cases characterized by infectious folliculitis due to various microbes, and that every chronic inflammation of the appendix should be considered *à priori* of a tuberculous nature.

A NEW HOSPITAL IN BALTIMORE.—The University of Maryland, which was founded in 1807 and is one of the oldest institutions in the country, is rebuilding the University Hospital. The new building will accommodate 175 patients and will cost about \$70,000. It will be built in the colonial style, to conform as far as possible to the old buildings of the University of Maryland.

THE MICROBE OF BALDNESS.—Great prominence has been given in the daily press to a discovery stated to have been made by M. Sabouraud, author of a well-known work on the biology of tinea, and superintendent of one of the laboratories at the Clinic of Dermatology. M. Sabouraud has succeeded in cultivating a microbe which he considers to be the cause of baldness, and which he has found to exist in great abundance in bald people. It invades the periphery of the hair follicles and brings about an influx of leucocytes, which choke the bulb and arrest its development. This is due to a special toxin which it secretes and which, according to M. Sabouraud, has a selective action on the hair follicle. A filtered culture injected into a rabbit is reported to have made all its hair come off. — *Paris Correspondence of the Lancet.*

Let all due haste be made in the preparation of an anti-alopecic serum!

NEW YORK.

PASSAGE OF THE BILL AGAINST ABUSE OF MEDICAL CHARITY.—It is reported that the stringent measure looking to the abolition of the abuse of medical charity in dispensaries, which was described in the JOURNAL for April 1st, has passed both houses of the Legislature, and is now awaiting the action of the Governor.

EXAMINATION OF SCHOOL CHILDREN.—The weekly report of Dr. Blauvelt, Chief of the Bureau of School Inspection, for the week ending April 10th,

shows that in the public and parochial schools of the city 7,398 children were examined, and 364 excluded. The number of cases of disease were as follows: Measles, 2; diphtheria, 13; scarlet fever, 1; croup, 3; whooping-cough, 4; mumps, 10; contagious eye-diseases, 59; parasitic diseases, 227; chicken-pox, 15; skin diseases, 19.

THE MORTALITY FOR THE FIRST THREE MONTHS OF SEVEN YEARS.—President Wilson of the Board of Health has sent to the Mayor a report in which the mortality for the first three months of the last seven years, and the annual death-rates per 1,000 of the population, are given as follows:

	Deaths.	Death-rate.
1891	10,212	24.90
1892	11,458	27.23
1893	11,844	27.33
1894	10,970	24.63
1895	11,728	25.34
1896	10,940	22.00
1897	9,937	20.35

It will thus be seen that not only has the death-rate been smaller in 1897 than in the first quarter of any of the other years, but that, notwithstanding the large increase in population, the actual number of deaths has also been smaller. The most gratifying statement in the report, however, is the announcement that the death-rate for 1897, 20.35, is the smallest that has ever been recorded for the same period of the year.

Miscellany.

AMERICAN PUBLIC HEALTH ASSOCIATION.

The Twenty-sixth Annual Meeting of the American Public Health Association will be held at Philadelphia, Pa., October 26 to 29, 1897.

The Executive Committee have selected the following topics for consideration:

- I. The Pollution of Water-Supplies.
- II. The Disposal of Garbage and Refuse.
- III. Animal Diseases and Animal Food.
- IV. Car Sanitation.
- V. Steamship and Steamboat Sanitation.
- VI. The Prevention of the Spread of Yellow Fever.
- VII. The Transportation and Disposal of the Dead.
- VIII. The Relation of Forestry to Public Health.
- IX. Nomenclature of Diseases and Forms of Statistics.
- X. Cause and Prevention of Infectious Diseases.
- XI. Public Health Legislation.
- XII. Cause and Prevention of Infant Mortality.
- XIII. Transportation of Diseased Tissues by Mail.
- XIV. River Conservancy Boards of Supervision.
- XV. The Period during which each Contagious Disease is Transmissible, and the Length of Time for which each Patient is Dangerous to the Community.
- XVI. Sanitation, with special reference to Drainage, Plumbing and Ventilation of Public and Private Buildings.
- XVII. Some Method of International Arrangement for Protection against the Transmission of Infectious Diseases.
- XVIII. Disinfectants.

XIX. Existing Sanitary Municipal Organizations of the Countries belonging to the Association, with a view to a Report upon those Most Successful in Practical Results.

The President of the Association is Henry B. Horlbeck, M.D., Charleston, S. C. The Secretary, Irving A. Watson, M.D., Concord, N. H. The Chairman of Local Committee of Arrangements, Benjamin Lee, M.D., 1532 Pine Street, Philadelphia, Pa.

TRAINED NURSES AND THE PUBLIC.

"PRIVATE nurses often suffer at the hands of the public from too much being expected of them—too much work in many cases, to sit up all night, and sometimes half the day, with only an hour or two for sleep, in a noisy room, with interruptions by foolish questioning—if nurse complains, the answer is ready, sister or wife sat up day and night for the first few days till they broke down; why should not nurse, and her trained to the work, do the same? They forget that nurse must not break down; if she does, she may have to starve. What they fail in doing for a day or two, nurse has to spend her life doing; and if overtired or sleepy she is the less a valuable nurse. Too much sympathy, indulgence which is bad for the patient and impertinent in the nurse, is often expected, and if not found, nurse is said to be so unsympathetic in her manner. Patients, too, expect that a nurse, like faith, can move mountains, that a little woman should be able to haul a sixteen-stone invalid up and down the bed.

"One nurse, having suffered much in the service of such a case, put her woes rather neatly by saying that the patient's friends expected her to be a judicious blend of an angel, a horse, and a steam-crane!

"There is, of course, another side to the story. A nurse in a middle-class house with few servants may sometimes be an intolerable burden. Airs and graces, meals at all odd hours to be carried up to her, constant ringing of bell for coals and hot water. If she expects the conveniences of a hospital in a private house, there will soon be friction.

"Her tongue often wags too freely. Gossip about previous patients, appalling and apocryphal stories of hospital life, its operations and its young doctors. Noise in the sick-room at night, and, worst of all, light for her book or her work, when the patient cannot sleep if a glimmer is seen in the room. Want of consideration in trifles. To hang an enema syringe to dry over a crucifix, will not be a way to win the heart of a high-church maiden. To turn the faithful old nurse out of her nursery will estrange, once and for ever, the shy and ailing child."

[From "The Relation of the Trained Nurse to the Profession and the Public," by Joseph Bell, M.D., F.R.C.S., *Scottish Medical and Surgical Journal*, April, 1897.]

CHARAKA SAMHITA.

THE sixteenth fasciculus of this quaint old medical treatise has recently appeared, and contains a great deal that is of interest to the medical archeologist.

The general causes (with their respective characteristics) of destructive plagues, etc., having been expounded, the root of those causes is explained as the

unrighteousness of the inhabitants of the cities and towns which are devastated by them.

In the Krita age, says the sage, men were endowed with energy, puissance stainless and abundant, capable of beholding in the flesh the deities, competent to ordain rules in respect of piety of conduct, and sacrifices; with bodies unacquainted with change, and compact as Himalayan adamant; with agreeable complexion and senses competent to discharge their functions; with strength, speed and prowess, like those of the deity of wind; with handsome hips, of agreeable statue and lineaments and excellent suppleness and growth; possessed of truth, sincerity, compassion, charity and self-restraint; observant of regulations of conduct, penances, fasts and vows, and freed from fear, attachment, malice, stupefaction of judgment, cupidity, wrath, grief, pride, disease, sleep, languor, fatigue, weariness, sloth, and all surroundings (in the form of family and property). In consequence, they all attained to unlimited length of life.

When the Krita age was expiring, in consequence of a few of the well-to-do having become covetous, their bodies became heavy. In consequence of the heaviness of the constituents of the body, fatigue appeared (as the result of labor). From fatigue came sloth. From sloth came the laying up of stores. From the laying up of stores came the desire of having as much as possible from all sources. From the desire to have as much as possible came cupidity or covetousness. Then, when the Krita age expired, from covetousness arose rivalry. From rivalry rose untruthfulness of speech. From this arose lust, wrath, pride, animosity, hostilities, fear, heart-burning, grief, anxiety of heart and other evils.

In the Krita age, righteousness diminished by a quarter. (Exactly how the decrease of righteousness was measured the sage does not tell us.) In consequence of this diminution of righteousness the virtues of land and the rest disappeared by a quarter. The food produced by the land lost a quarter of its virtues, and the physical forms of human beings, not properly supported by the crops, lost a quarter of their virtues and became surcharged with heat and wind, and a prey to diseases and decrepitude.

Of interest later in this chapter is the list of the classes of patients the Hindu physician should not attempt to treat. They are:

(1) One that is not disposed to remove the cause of censures directed to one's self.

(2) One that is very poor. (The objection to treating the very poor, says the translator, is based upon his inability to conform to the instructions of the physician.)

(3) One that has no attendants to look after him.

(4) One that is full of pretensions regarding his own skill as a physician.

(5) One that is of a fierce temper.

(6) One that is envious of other people.

(7) One that is exceedingly addicted to unrighteous acts.

(8) One that is exceedingly weak in strength, flesh and blood.

(9) One that is suffering under an incurable disease.

(10) One in whom the symptoms of the near approach of death have discovered themselves.

By treating a patient of any of these kinds, the physician incurs both sin and infamy.

The fourth lesson, which is included in this fascicu-

lus, treats of the methods of diagnosis of diseases; and the fifth of the various ducts of the body and their diseases.

THE HEIGHT AND THE VELOCITY OF THE FLIGHT OF A FLOCK OF GESE MIGRATING NORTHWARD.

MR. H. H. CLAYTON, writes to *Science* under date of March 22d, that on that morning while Mr. A. E. Sweetland and he were measuring clouds, at the ends of a base line 1178.4 metres in length, extending from the Blue Hill Meteorological Observatory to the base of Blue Hill, they succeeded in measuring, with their cloud theodolites, the height and the velocity of a flock of geese. So rapid was the flight that the flock was visible only about two minutes, but during that time two sets of measurements were taken with the theodolites on the leader of the flock. The calculations gave the height as 905 feet above the Neponset River valley, or 960 feet above sea level, and the velocity of flight as 44.3 miles an hour. The direction of flight was from southwest to northeast.

The wind at the time of the measurement was from the west northwest, with a velocity of eight miles an hour.

On a previous occasion, as described in *Science*, January 1st, p. 26, these observers found a flock of ducks flying from the northeast at a height of 958 feet, with a velocity of 47.8 miles an hour. The close agreement between the two results is suggestive.

Obituary.

JOHN O. DOW, M.D.

At the last meeting of the Middlesex (East) District Medical Society the following resolutions were read and adopted:

MELROSE, April 20, 1897.

The Middlesex East Medical Society places on record the following tribute to the memory of Dr. John O. Dow, of Reading:

From his first advent in this district in 1874, Dr. Dow very soon became known as a practitioner of marked ability and skill. In a short time he entered upon a large and successful practice—a practice which was won entirely by his own reputation and ability, and never by unfair or unfriendly means. Dr. Dow was to every one who knew him, a true friend, not only to his patients but also to his brother practitioners. His peculiarly gentle demeanor in the sick-chamber and at the bedside of his patients won for him a place in their hearts which was never forgotten.

At the meetings of our Society Dr. Dow appeared to the casual observer to be of a quiet, and reticent nature; but this was due to genuine modesty and disinclination to obtrude his opinions, and his immediate associates, who had occasion to consult him often in practice, invariably found his advice of the highest professional value, and given in such a manner as to be not only profitable to the patient, but also to increase his confidence in the attending physician.

To the younger members of the profession the character of Dr. Dow may especially be commended as an example worthy of imitation, both as an upright and honorable citizen, and as a physician of unswerving devotion to one of the noblest of all professions. It is not too much to say that to Dr. Dow pre-eminently belonged the title of "Good Physician."

SAMUEL W. ABBOTT,
CHARLES DUTTON,
ARTHUR H. COWDREY.

METEOROLOGICAL RECORD

For the week ending April 10th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Northampton	16,738	—	—	—	—				
Newburyport	14,554	6	3	—	33.33				
Amesbury	10,920	—	—	—	—				

Deaths reported 3,523; under five years of age 1,102; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping cough, erysipelas, diarrheal diseases and fever) 330, acute lung diseases 616, consumption 580, diphtheria and croup 141, diarrheal diseases 52, scarlet fever 34, whooping-cough 32, typhoid fever 32, measles 19, cerebro-spinal meningitis 16, erysipelas 4.

From whooping-cough Philadelphia 10, New York 7, Chicago 6, Brooklyn 4, Baltimore 2, Boston, Washington and Everett 1 each. From typhoid fever Chicago 8, Philadelphia 7, Boston, Cleveland and Pittsburg 4 each, New York 3, Brooklyn and Fall River 1 each. From measles New York 6, Chicago 5, Brooklyn and Boston 2 each, Baltimore, Cincinnati, Pittsburg and New Bedford 1 each. From cerebro-spinal meningitis Boston 6, New York 4, Somerville 3, Washington, Lawrence and Nashville 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,992,524, for the week ending April 3d, the death-rate was 18.3. Deaths reported 3,866; acute diseases of the respiratory organs (London) 282, whooping-cough 105, measles 89, diphtheria 66, diarrhea 33, scarlet fever 28, fever 23.

The death-rates ranged from 34.8 in Bolton to 12.6 in West Ham; Birmingham 17.6, Blackburn 14.7, Brighton 14.2, Croydon 12.9, Gateshead 13.4, Hull 16.2, Leeds 17.8, Leicester 17.9, Liverpool 22.7, London 17.6, Manchester 23.9, Newcastle-on-Tyne 19.4, Nottingham 24.0, Portsmouth 17.1, Sheffield 15.9, Sunderland 17.4, Swansea 15.1.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 10, 1897, TO APRIL 16, 1897.

FIRST-LIEUT. LEIGH A. FULLER, assistant surgeon, will proceed from Fort Meade, S. D., to Fort Harrison, Mon., and report for temporary duty at that post, during the absence on leave of CAPTAIN EDWARD C. CARTER, assistant surgeon.

The leave of absence granted FIRST-LIEUT. GEORGE D. DE SHON, assistant surgeon, Washington Barracks, D. C., is still further extended to include May 1, 1897.

Leave of absence for one month, with permission to apply for an extension of two months, is granted CAPTAIN EDWARD C. CARTER, assistant surgeon, Fort Harrison, Mon.

LIEUT. GUY C. M. GODFREY, assistant surgeon, is ordered by the Secretary of War, as necessary for the public service, to proceed to St. Paul, Minn., and report in person to the commanding general, Department of Dakota, for temporary duty in that Department, and when his services shall no longer be required, to return to his proper station at Fort Sheridan, Ill.

CAPTAIN NATHAN S. JARVIS, assistant surgeon, is relieved from duty at Willet's Point, N. Y., to take effect on the expiration of his present leave of absence and ordered to Fort Huachuca, Ariz., instead of Fort Clark, Tex., for duty.

PROMOTIONS.

FIRST-LIEUTS. FRANCIS A. WINTER and WILLIAM E. PURVIANCE, assistant surgeons, to be assistant surgeons with the rank of Captain, after five years service, March 9, 1897.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday evening, April 26th, at 8 o'clock.

Dr. William T. Porter will read on "The Physiology of the Sympathetic Nerve."

Dr. F. B. Lund will read on: "Enteroptosis and Movable Kidney." Drs. Thomas Dwight, J. W. Elliott, F. S. Matson and A. K. Stone have been asked to take part in the discussion.

JAMES G. MUMFORD, M.D., *Secretary*, 197 Beacon St.

SUFFOLK DISTRICT MEDICAL SOCIETY.—The Section for Obstetrics and Diseases of Women will meet at 19 Boylston Place, Wednesday, April 28, 1897, at 8 p. m.

The following papers will be read:

A. K. Stone, M.D., "Enteroptosis as a Clinical Factor in the Diseases of Women."

Emma L. Call, M.D., "Acute Tuberculosis in Puerperal Women."

THE SUFFOLK DISTRICT MEDICAL SOCIETY, SURGICAL SECTION.—Owing to the fact that the Medical Congress in Washington comes on Wednesday, May 5th, the last meeting of this Section for the year will be held at the Medical Library, 19 Boylston Place, on Friday evening, April 30th, at 8 o'clock, instead of on the above date.

At 8.05 p. m. "The Incision and Method of Procedure in the Removal of Diseased Processes in the Neck, occupying the Space behind the Sterno-mastoid Muscle," by Dr. Frank Hartley, of New York. The paper is a description of Dr. Hartley's operative method in such cases, and the subject is considered under the headings: "The Incision," "The Exposure of the Field," "The Resulting Scar." Dr. G. H. Monks will open the discussion of this paper.

At 8.45 p. m. "Projection Demonstration of an Unusual Degeneration in the Spinal Cord due to Metastatic Carcinoma of the Spine," by Dr. J. H. Wright.

At 9 p. m. "Deformities of the Feet in Art," by Dr. E. H. Bradford. Illustrated by the stereopticon. Synopsis: A description of the shape of the foot as represented in Barbaric, Egyptian, Greek, Roman and Modern art; a description of the shape of a normal foot, and of the foot as distorted by footwear; a description of the Greek sandal and its effect upon the foot; evidence of sandal distortion seen in Greek and Roman art which is copied to modern art.

PAUL THORNDIKE, M.D., *Secretary*, 214 Marlborough St.

POSTPONEMENT.

The address on "Medical Jurisprudence" by Hon. Hosea M. Knowlton, announced in the last issue of the JOURNAL for Friday evening, April 23d, has been postponed.

RECENT DEATHS.

FRED WEBSTER WHITEMORE, M.D., M.M.S.S., died in Cambridge, April 14, 1897, aged forty-five years.

WILLIAM GOODNOUGH WHEELER, M.D., M.M.S.S., died in Chelsea, April 17, 1897, aged seventy-six years.

BOOKS AND PAMPHLETS RECEIVED.

A Hot Operating Table and Its Advantages. The Mechanism and Diagnosis of Traumatic Cerebral Lesions. Case of Intussusception due to Invagination of Meckel's Diverticulum; Operation, Recovery. By J. W. Perkins, M.D., Kansas City, Mo. Reprints. 1895-96-97.

The Use of Antitoxic Serum in the Treatment of Diphtheria under the Supervision of the New York City Health Department, with a *Résumé* of the Published Reports on the Subject. By Herman M. Biggs, M.D., of New York, and Arthur R. Gnerard, M.D., of New York. Reprint. 1896.

A Manual of Physiology, with Practical Exercises. By G. N. Stewart, M.A., D.Sc., M.D. (Edin.), D.P.H. (Camb.), of Downing College, Cambridge; Professor of Physiology in the Western Reserve University, Cleveland, etc. With numerous illustrations, including five colored plates. Philadelphia: W. B. Saunders. 1897.

Trifacial Neuralgia; Ligation of Common and External Carotids; Report of a Case, Age Ninety-seven Years. Anal Fistula, Peritonitis, Laparotomy, Recovery. Surgical Melange. Twelve Deaths. Chest Surgery. Branchial Cysts; Case; Excipitation; Recovery. By Merrill Ricketts, Ph.D., M.D., Cincinnati, O. Reprints. 1896.

Lectures on Renal and Urinary Diseases. By Robert Saundby, M.D., Edin., Fellow of the Royal College of Physicians, London; Emeritus Senior President of the Royal Medical Society; Fellow of the Royal Medico-Chirurgical Society; Member of the Pathological Society of London. With numerous illustrations. Second edition. Philadelphia: W. B. Saunders. 1897.

An Account of the Life and Works of Dr. Robert Watt, Author of the "Bibliotheca Britannica." By James Finlayson, M.D., Physician to the Glasgow Western Infirmary and the Royal Hospital for Sick Children; now Librarian to the Faculty of Physicians and Surgeons, Glasgow, etc. With a portrait. London: Smith, Elder & Co. 1897. [All rights reserved.]

Diphtheria and Antitoxin. By Nestor Tirard, M.D., Lond., Fellow of the Royal College of Physicians; Fellow of King's College, London; Professor of Materia Medica and Therapeutics at King's College; Physician to King's College Hospital and Senior Physician to the Evelina Hospital for Sick Children. London: Longmans, Green, & Co. 1897.

A Pictorial Atlas of Skin Diseases and Syphilitic Affections. In photo-lithochromes from models in the Museum of the Saint Louis Hospital, Paris. With explanatory wood-cuts and text by Ernest Besnier, A. Fournier, Tenneson, Hallopeau, Du Castel, Physicians to the Saint Louis Hospital, with the co-operation of Henri Finkard, Curator of the Museum, Secretary, L. Jaquet. Edited and annotated by J. J. Pringle, M.B., F.R.C.P., Physician for the Department for Diseases of the Skin at the Middlesex Hospital, London. Part VIII. London: The Rebus Publishing Co. Philadelphia: W. B. Saunders. 1897.

The Retrospect of Practical Medicine and Surgery, being a half-yearly Journal containing a Retrospective View of Every Discovery and Practical Improvement in the Medical Sciences. Edited by James Braithwaite, M.D., Lond., Obstetric Physician and Surgeon to the Leeds General Infirmary, late Lecturer on Diseases of Women and Children, Leeds School of Medicine; Fellow and late Vice-President of the Obstetrical Society of London, etc.; assisted by E. F. Trevelyan, M.D., Lond., B.Sc., M.R.C.P., Assistant Physician to the Leeds General Infirmary, Professor of Pathology, Yorkshire College, Leeds. Volume CXIV, January, 1897. New York: G. P. Putnam's Sons. 1897.

A Practical Treatise on Diseases of the Skin for the Use of Students and Practitioners. Fourth and revised edition by James Nevins Hyde, A.M., M.D., Professor of Skin and Venereal Diseases, Rush Medical College, Chicago; Dermatologist to the Presbyterian, Angustana and Michael Reese Hospitals of Chicago, and Consulting Dermatologist to the Chicago Hospital for Women and Children, and Frank H. Montgomery, M.D., Lecturer on Dermatology and Genito-Urinary Diseases and Chief Assistant to the Clinic for Skin and Venereal Diseases, Rush Medical College, Chicago; Attending Physician for Skin and Venereal Diseases, St. Elizabeth's Hospital, Chicago. Illustrated with 110 engravings and 12 plates in colors and monochrome. Philadelphia and New York: Lea Brothers & Co. 1897.

Original Articles.

THE TREATMENT OF OLD DISLOCATIONS OF THE SHOULDER.¹

BY F. B. LUND, M.D.,

Surgeon to Out-patients, Boston City Hospital; Assistant in Anatomy, Harvard Medical School.

THE number of old dislocations of the shoulder which present themselves for treatment at surgical clinics is fortunately becoming smaller from year to year. Thanks to the wide publication of the work of Kocher and others on recent dislocations and their reduction, by far the greater number of dislocations are reduced as soon as seen by the surgeon or general practitioner. Notwithstanding this fact, however, a certain number of patients with old dislocations present themselves at the clinics, some of whom have never previously consulted a surgeon, and a few who have been unfortunate in their choice of a surgical adviser. By the personal observation of a few of those, which I have been kindly allowed to examine by members of the visiting staff at the Boston City Hospital, and by personal experience of some of the difficulties of their reduction, I was led to look up the question of their treatment, and see what light, if any, could be thrown upon it by an examination of the literature of the subject and of the hospital records. The result, though not entirely satisfactory, owing perhaps to the small experience in these cases which comes to any one man, and the resulting meagreness of the literature of the subject, has nevertheless been that certain interesting and important points with reference to the treatment of these injuries have been brought out.

In the first place, as is well known, the difficulty of reducing dislocations of the shoulder after the lapse of a very short period, say two weeks, increases directly in proportion to the interval of time. Dislocations of less than two weeks' duration are almost as easy to reduce as fresh dislocations; and since Kocher has shown that all fresh, uncomplicated dislocations are reducible by manipulative methods, all dislocations two weeks or less old are capable of reduction by methods of manipulation. The same anatomical characteristics which render the shoulder-joint the most liable to dislocation of any joint in the body in themselves facilitate reduction. It is comparatively easy for the large globular head of the humerus to slip out of the shallow cup of the glenoid cavity, if the necessary rupture of the capsule is present, and the rupture of the capsule made by the head of the humerus is always big enough to let the head slip back, if it is properly opened by Kocher's, or other methods of manipulation. The free play of the head of the bone under the arch of the acromion, the comparative looseness of the capsule, all render dislocation and reduction comparatively easy. The tendons of most of the muscles about the joint are short, and so intimately blended with the capsule as not to afford obstacles to reduction by slipping in between the head of the bone and the socket. Even the long tendon of the biceps, which at first thought one would suppose most likely to fall in between the head and the socket, so as to prevent reduction, is held up out of the way by its special fibrous channel in the capsule of the joint, from which, in the ordinary subcoracoid dislocation, it is never displaced.

The manipulative methods for reduction of the shoulder-joint, especially the simple, beautiful and efficient method devised by Kocher, of Berne, are too well known to need discussion here. Suffice it to say that Kocher's method is to be preferred in all fresh dislocations, as being the simplest and easiest, as requiring no direct pressure on the axillary vessels and nerves, and as being successful in a large proportion of cases without anesthesia.

Dislocations of the shoulder a week or less old, then, should be reduced in all cases, preferably by Kocher's method.

After the head of the humerus has been out under the coracoid process for two weeks or more, however, difficulties in the way of reduction begin to present themselves. The unruptured posterior portion of the capsule, which has been tightly stretched across the glenoid cavity, has become in old cases rather firmly adherent to that cavity. The head of the humerus has become adherent as it lies nipped between the biceps and coraco-brachialis muscles and the neck of the scapula. The posterior rotators of the humerus, the supra-spinatus, infra-spinatus and teres minor muscles, have become so paralyzed by continued stretching as to no longer afford efficient aid to the surgeon in pulling the head of the bone back into place. In order to successfully reduce the dislocation, the head of the humerus must be freed from the adhesions which bind it into its new position, the adherent capsule must be peeled off from the surface of the glenoid cavity, and the head of the humerus forced back under the acromion, lifting the adherent capsule and the tendons of the posterior rotators out of the way. After a still longer time, say two or three months, has elapsed, the neck of the humerus has become fixed under the coracoid by firm fibrous adhesions, the capsule has become so firmly bound down to the glenoid cup as to actually form a part of it, and the atrophy of the deltoid and posterior scapular muscles bear witness to the fact that even if the dislocation should be reduced, these muscles would require a long course of training in order to recover strength enough to hold the head of the humerus up in place in its socket. The important part played by these muscles in holding the head of the bone in place is shown by the subluxation of the head of the bone which takes place when they have become paralyzed. In paralysis of the deltoid and scapular group without dislocation we have seen the head of the humerus fall downward and forward out of its socket, within the loose capsule of course, to such an extent that the head got over the anterior edge of the glenoid, the arm was lengthened nearly an inch, and this, together with the flattened deltoid, gave a typical picture of a dislocation. By grasping the humerus, however, the head of the bone could be easily lifted into position, but the paralyzed muscle could not hold it.

Now with regard to this adhesion of the posterior portion of the capsule to the glenoid cup. The capsule, of course, is more or less thickened by the inflammatory processes, and fills up the cavity, adhering over its broad surface, so that it cannot be stripped off. It is in this class of cases that we read in the records, that the head was almost reduced, but could not quite be made to get into perfect position, that it remained just on the edge of the glenoid; that although something had been gained, reduction could not be considered quite satisfactory. What has hap-

¹ Read before the Surgical Section of the Suffolk District Medical Society, February 3, 1897.

pened in these cases, is in all probability this: that since the efforts at forcing the head back into place fails to strip the adherent capsule off the surface of the glenoid, the capsule, by the violent efforts at reduction, is ruptured opposite the anterior edge of the glenoid, and the head forced back over the glenoid is kept out of its socket by the part still adherent. Unless that adherent capsule be peeled off, the complete and satisfactory reduction of the head of the bone will be, and is, impossible. The question suggests itself, Why not open the joint in these cases by operation, and peel off the capsule, or gouge it out so as practically to make a new socket, by a method analogous to Hoffa's operation in congenital dislocation of the hip, so as to allow complete reduction of the dislocation? The answer to this query opens up the wide question of operative reduction of dislocations of the shoulder, which will be considered later on.

With reference to the obstacles to reduction in cases of old dislocations of the shoulder, I may refer to Kocher's article in the *Deutsche Zeitschrift für Chirurgie*, 1890, p. 423, in which we find the details of his findings at operation or autopsy on eight cases ranging in age from five weeks to eleven months. In some cases the capsule was adherent to the glenoid, as described above, in others the rent in the capsule had healed so completely behind the head of the bone as to prevent reduction. In seven of the eight cases, the great tuberosity had been pulled off, and in several portions of the capsule were greatly thickened and at times calcified. The glenoid cavity was sometimes filled up with a thick, rough deposit of bone. The head of the humerus had in one case of six months' standing formed for itself a new socket in the front of the neck of the scapula. The familiar picture of such a socket upon a scapula from a case of Sir Astley Cooper's figured in Stimson and Hamilton's work on fractures and dislocations, you will, doubtless, most of you remember. An interesting fact about this case is that in one it is classed among acromioclavicular and in the other among glenoid dislocations.

Such being the pathological conditions found in cases of old dislocations of the humerus, what is to be our method of procedure in attempting reduction? In order to answer this question intelligently we must consider the relation of the danger attending attempts at reduction to the severity of the symptoms which we are endeavoring to relieve, the prospect of successful reduction, and the advantages gained thereby.

What are the symptoms for which our patients apply to us for relief? In the first place, we find that these old dislocations of the shoulder present a very different picture from the fresh dislocations. The atrophy of the deltoid and scapular muscles allow the bony landmarks to stand out in bold relief, and the diagnosis is so easy as to admit of no doubt whatever. The elbow is not held away from the side as in fresh dislocations, as the deltoid has been stretched sufficiently to allow it to fall easily in. Rotation of the head of the humerus is absent or nearly so, abduction of the arm is possible only by elevation of the scapula, and very rarely can be carried to a right angle. Forward elevation is possible to a right angle, and backward not at all. All motions of the forearm, elbow and hand are normal. The patient can do light work, fetch and carry, but is usually unfitted for the heavy work of a laborer.

The above picture is doubtless recognized to be

more favorable than certain cases which we have all of us seen, in which pain, edema, paralysis, etc., from pressure of the head of the bone upon the brachial flexus, are present; but it is proposed in this discussion to deal with the average cases. Cases in which the latter symptoms are present, require, of course, more heroic treatment.

Old cases are also occasionally seen in which such excellent motion of the arm has been obtained, that the hand can be easily placed on the head, and almost all movements performed with ease. Such a case has been recently seen by the writer at the Boston City Hospital in the service of Dr. H. W. Cushing.

In the treatment of these cases, manipulative methods, as the simplest and least radical, will, of course, first be tried, and the question be considered as to what manipulative methods combine the greatest effectiveness, with the least danger. And the danger in these cases is of two sorts: first, fracture of the humerus, not a very uncommon accident; and a second and much more serious mishap, rupture of the brachial artery or vein. This accident happened to no less eminent and careful a surgeon than Sir Joseph Lister, who tied the artery, but lost his patient from shock. The autopsy in his case showed, in the first place, atheroma of the vessel, a finding which should make us cautious in the application of violent manipulative methods in aged patients, and also revealed beautifully the mechanism by which the injury took place. Although the attempt was made only eight weeks after the dislocation, at the autopsy was found a "strong fibrous band, connecting the head of the humerus with the coracoid process, and intimately blended by condensed tissue with the sheath of the axillary artery, which lay directly over it. Strong traction made upon this band, was necessarily communicated to the axillary artery, which had a small hole torn in its side. This autopsy is of interest, as showing that rupture of the artery is more likely to take place from traction upon fibrous bands, which is essential to all manipulative methods of reducing dislocations of the humerus, rather than from pressure, as over a pad or heel in the axilla, which pressure, if properly applied, ought to be behind the artery, rather than directly upon it. Although but few cases of rupture of the axillary artery in attempts to reduce dislocations of the shoulder have been published, most surgeons of experience have either seen such cases or heard of them. Violent manipulations should then be avoided in old patients or those with atheromatous arteries.

Stimson² reported 44 cases of rupture of the axillary artery or vein obtained from the literature of the subject up to that date. In more than half the cases, the dislocation had existed less than three weeks. In not more than a third of them was it reasonably certain that the injury was caused by the attempts at reduction and not by the dislocation itself. The danger of the accident is attested by the fact that only 12 of the 44 cases recovered; 31 died, and in one the result was not known. Of 20 cases not operated upon six recovered and 14 died. Of 14 in which the subclavian was tied five recovered and eight died; of six cases in which an incision was made in the axilla and the artery tied above and below the wound all died. Of four in which the limb was disarticulated one recovered and three died.

² *Annals of Surgery*, 1885.

In order to avoid these dangers, Kocher in his article above referred to, advocated the application in these cases of his own method for the reduction of fresh dislocations, slightly modified to meet the requirements arising from the adhesions and other changes present in old dislocations. These modifications consisted chiefly in that the manipulations should be made more slowly, that the elbow should be carried in the first movement a little back of the mid-axillary line instead of directly to the side, that the arm should be held for some time in complete outward rotation, and that during the third movement, lifting the elbow in the sagittal plane, a pad might be placed in the axilla to act as a fulcrum in prying the head of the bone outward into position. Kocher has found this method successful in reducing 25 out of 28 old dislocations, three of them being over four months old. He had fractured the humerus, however, in three cases, a rather large proportion.

The advocacy of this method in old dislocations by so great an authority as Kocher has led to its extensive trial in old dislocations, and in other hands it has apparently not met with such good success. I think it can be shown that this method in reality is attended with great danger of fracture of the humerus. The liability of the humerus to fracture under twisting strains has been shown by Monks;³ and the second movement of Kocher's method, extreme outward rotation, the forearm at right angles and used as a lever, exposes the humerus, if its head is firmly held by adhesions, to a twisting strain of extreme severity.

Morton⁴ reports three cases in which this accident has happened in the attempt to reduce old dislocations by the Kocher method. In his own case the fracture, which was "very oblique through the head and neck of the bone" (probably a spiral fracture), occurred just as the arm, after being completely rotated outward, had been raised to the termination of the third movement, across the chest. Here we have twisting strain combined with leverage, a very dangerous combination if the head of the bone is firmly held by adhesions. The occurrence of at least one other case in which fracture resulted from the employment of this method is known to the writer. As Morton suggests, it is unwise to employ this method in old dislocations unless previous manipulations have already been employed to rupture as far as possible the adhesions that hold the head of the humerus in its new position.

Now what manipulations are the safest and most efficient to employ in breaking up adhesions between the head and neck of the humerus and the scapula? It is self-evident that we must first fix the scapula, before we attempt to move the humerus on it, whatever method we adopt, else the whole shoulder girdle will follow the excursions of the humerus, and no motion between the scapula and the latter will take place. In the reduction of fresh dislocations by Kocher's method, without anesthesia, the scapula is beautifully fixed by involuntary spasm of the muscles, the edge of the glenoid being firmly held as a fulcrum for the motions of the head of the bone. In these old dislocations, however, we will find it necessary to resort to anesthesia in almost all cases, and must find some artificial means of fixing the scapula. This is done rather efficiently by the surgeon's heel as it is forced into the

axilla in Sir Astley Cooper's method, a method which the writer has found efficient in reducing one case of old dislocation, and may be accomplished, though rather inefficiently by the hands of an assistant embracing the trunk of a patient from the opposite side, and clasped over the scapula. The most efficient method, and one which was successful in the remarkable case of Dr. Burrell's, was that of passing folded sheets over the shoulder and around the body, these sheets being held by assistants.⁵

Rapid and forcible rotation of the humerus back and forth, within short limits at first and gradually increasing, is probably the safest method of breaking up adhesions. In performing this rotation the forearm should not be used as a lever.

Extension of the arm above a right angle to the body stretches the axillary vessels and brachial plexus across the head of the humerus, and is attended with danger of injuring them. It should therefore be avoided.

All manipulative methods in old cases require the application of considerable force. The amount of force which it is safe to apply must be left in each individual case to the judgment of the surgeon. Atheroma of arteries and firm adhesions in aged patients contraindicate great force. In young patients a very considerable degree of force, if carefully and intelligently carried out, may be safely employed. Dr. Burrell's successful reduction after eight months, it will be remembered, was in the case of a muscular man twenty-three years of age. The probability of success in these cases, decreases directly with the length of time since the accident happened.

We are now confronted by the question, If manipulative methods fail, shall operative methods be resorted to for reduction? In order to answer this question intelligently we must consider, first, the extent of the disability which we are attempting to relieve; second, how much good will probably result from operative measures; and third, what the danger of such methods is, and their prospect of success.

The first question we have already answered before considering manipulative methods and their dangers.

The second can only be answered by a brief consideration of the various operative methods in turn.

The methods which have been proposed for the operative treatment of old dislocations of the shoulder are, first, osteotomy of the surgical neck with formation of a false joint (Mears⁶); second, subcutaneous section of the capsule and reduction (Pollakillon⁷); third, reduction by open incision; fourth, resection of the head of the humerus.

The subcutaneous section of the neck of the humerus has failed to show good results. The subcutaneous section of the capsule, is a survival of pre-antiseptic methods. The blind section of the adhesions about the head of the humerus is manifestly attended with great danger of wounding arteries and nerves, and the open incision is manifestly simpler, easier and safer. The reduction by open incision and the resection of the head of the humerus, remain as the only methods worthy of serious consideration.

Reduction by open incision was first performed by Wattman of Insbrück⁸ in 1820. He succeeded in

effecting reduction, but (strange to say!) suppuration followed, but healing finally took place, and the patient left the hospital (time not stated) having still great limitation of motion.

The introduction of antiseptic methods naturally encouraged further attempts of the sort; and in 1888 Knapp published a report of 12 cases, of which two died, one of sepsis and the other of delirium tremens. Of the remaining 10, one attempt resulted in fracture of the surgical neck with pseudarthrosis, three in necrosis of the head of the humerus, necessitating subsequent extraction; in two the reports were incomplete, and in the remaining four material functional improvement resulted. Surely not a very brilliant showing for the operation. Of operations by resection of the head of the humerus, he had collected 20 cases, of which four were fatal. Of the remaining 16, the later reports were inadequate in six, leaving 10 cases in which the results were in part equal to those of arthrotomy, and in part decidedly better.

The results of Kocher's experience with bloody reposition, published in 1890,⁹ are scarcely more reassuring. Of eight cases on which he operated he found only one to be uncomplicated by fracture of the tuberosities or of the glenoid rim. In six bloody reposition was done, and in two of these was final improvement in the use of the arm noted. One died of sepsis. Of two resections of the humeral head one gave a good functional result.

Both bloody reposition and resection of the humeral head have, according to the showing of these two writers, not given results sufficiently brilliant to encourage their general adoption. Resection of the humeral head has, however, the advantage that it can be successfully carried out in cases where owing to the filling up of the joint cavity or other causes, bloody reposition is unsuccessful.

We cannot leave the question in 1896, however, exactly where it was in 1890; and let us now see what has been accomplished in this field since that date. The gloomy showing given above naturally failed to encourage many surgeons to attempt operative relief in shoulder dislocations, but a certain number of cases have presented themselves for treatment in which any slight prospect of improvement was to be preferred to the present pitiable condition of the patient, and in which operative relief has been undertaken. Such cases are those in which pressure of the humeral head upon the axillary vessels and nerves has resulted in unbearable pain and swelling of the arm, and two cases in which the patient was rendered absolutely helpless by a double irreducible dislocation. I think it will appear, that the results of these more recent operations have been more satisfactory than those of the earlier cases reported by Kocher and Knapp.

A Pearce Gould¹⁰ reports a case in which he performed reduction by open incision upon a dislocation of fourteen months' standing, after manipulative methods had failed. "After nine months rotation of the shoulder was nearly perfect, and all the usual movements could be performed." The man was able to perform severe and continuous manual labor, the only injury remaining being some disability of the hand, due to damage to the ulnar nerve.

Watson Cheyne¹¹ showed a case upon which a simi-

lar operation had been performed in a dislocation of four months' standing. The result was less satisfactory than in the preceding case, but the man was enabled to do his work as a French polisher.

Sir Joseph Lister¹² had the rare good fortune of operating successfully on two cases of double irreducible dislocation of the shoulder. The propriety of any operative attempts at relief of such cases as these can hardly be questioned. In the second case the man was unable to put either hand to the gluteal region; the pitiable dependence resulting from which condition is obvious.

In Lister's first case, a robust laborer of forty-seven, with a double dislocation of four months' standing, bloody reposition was done upon each shoulder at a separate operation. The result was complete recovery of every motion of the shoulder except ability to lift the arm above a horizontal level, ability to perform hard manual labor, and recovery of the full size of the deltoid muscle. In the second case, that of an epileptic, both of whose shoulders had been dislocated for seven months, two operations were also done, with the result that the man was enabled to earn his living on a farm, and to perform very hard manual labor.

Polsson¹³ reports five cases of arthrotomy and reduction of old dislocation, in three of which good functional results were obtained. In one suppuration necessitated subsequent resection of the head of the humerus, and in one death resulted from the operation.

MacCormac¹⁴ reports a case in which arthrotomy had to be followed by resection on account of suppuration.

Owen¹⁵ reports a case of resection for old dislocation.

Monks¹⁶ reports a case of resection of the head of the humerus in a case of old dislocation attended by pain, atrophy of the muscles, and swelling of the arm from pressure on the nerves and vessels, in which the operation gave an excellent result.

Delbet¹⁷ reports a case of resection of the head of the humerus for an old dislocation in which attempts at reduction by arthrotomy by a posterior incision had been unsuccessful. The functional result of the operation was excellent. As a result of this experience he condemns the posterior incision, which he had been led to attempt by the results of experiment upon the cadaver. In his paper he gives a list of the reported cases of arthrotomy and resection, showing that there had been up to that time 28 arthrotomies reported, three of which died, a mortality of 10.72 per cent. Of 34 resections five had died, a mortality of 14.36 per cent. Although the mortality of resection is a little higher, the number of cases is too small and extends over too long a time to be of much value for purposes of comparison.

Arthrotomy would seem to be a more difficult operation than resection, and it is a little surprising that the latter should show a higher mortality. Of the 25 cases which recovered from the operation by arthrotomy, the results were good or fairly good in 12; five results were poor. In four secondary resection had to be done, and in three results were unknown. In one

¹⁰ British Medical Journal, February 27, 1892.

¹¹ Loc. cit.

the attempt resulted in fracture of the humerus and subsequent pseudarthrosis.

Polosson's results are not included in the statistics of Delbet. If these are added, we have 33 cases, with 15 good results, six poor results, five secondary resections, four deaths, and three cases not heard from; mortality 9.1 per cent.

Collecting the cases since 1890, we find arthrotomies as follows:

Gould, one case. Result good.
Cheyne, one case. Result good.
Lister, two cases. Result good.
Polosson, five cases. Three results good, one poor, one death.
MacCormac, one case. Result poor.

This gives 10 cases, with six good results, two poor results and one death. In the two cases in which the result was unsatisfactory, secondary resection was performed on account of suppuration.

Of 29 cases which survived the operation for resection in 13 the results were satisfactory (to these may be added the cases of Monks, McCormac and Owen, making 37 cases with 16 good results), in five the results were mediocre, in two bad, and in six they were unknown. The mortality is reduced to 13.5 per cent.

Schede has stated that the results of arthrotomy with reduction are far preferable to those of resection; but, as Delbet points out, the results are not comparable, and each case must be judged upon its merits. In the large majority of cases, the operation is begun with the attempt at reduction, and if this is unsuccessful, resection is performed. Resection can be performed secondarily if necrosis of the head of the humerus or long-continued suppuration should follow arthrotomy, and these accidents may be avoided by strict asepsis.

Arthrotomy with reduction should be our ideal, as it more nearly restores the normal conditions of the joint and surrounding structures. It is, however, a very difficult operation, more difficult than resection, and in cases where on opening the joint we find the head of the humerus enlarged by bony new growth, so that it cannot be forced into the glenoid cavity, it must be resected. When the glenoid cavity cannot be satisfactorily opened up so as to receive the head with a fair probability of its staying in place, resection should likewise be done.

It is a question whether, as Delbet says, cases in which reduction by arthrotomy is attended by great difficulty, so that extensive division of the muscles about the joint is required, and the head of the humerus will be held tightly by firm adhesions when healing has taken place, resection should not be preferred to arthrotomy as a primary measure. In Lister's and Gould's very successful cases, however, the muscles reunited after extensive section, and an excellent functional result was attained, so that they speak strongly in favor of arthrotomy. After resection the power of rotation, which was retained in these cases, will be necessarily lost, as the attachments of the rotations to the tuberosities are removed. If resection is necessary, only so much of the head of the bone should be removed as will enable the operator to slip the upper end into the socket. Too extensive removal gives a loose flail joint, too economical a cut exposes to danger of ankylosis.

I have collected from the records of the Boston City Hospital since 1882 the results of 24 cases which as will be seen have been treated by manipulation only, in all except two cases.

The results in these cases are of interest as show-

ing the prospect of success by manipulative methods at different times after the injury, and as showing that after a certain very limited period, the dislocation if reduced at all must be with rare exceptions reduced by open incision.

Dislocations of two weeks' and less duration are considered as fresh dislocations, and do not enter into our treatment of the subject. Cases in which the note reads, "reduction fairly successful," or "head of bone in fair position," have been classed as unsuccessful cases. I found records of four dislocations of from two to three weeks' standing, all of which were reduced successfully by manipulation. Three were reduced by traction downward and outward, with pressure upon the head of the humerus in the axilla. In one case in which the head of the humerus was said to lie under the clavicle which was reduced by extension at right angles to the body, we find it noted that pain in the arm, numbness of the fingers, paralysis of the deltoid with reaction of degeneration, and weakness of other muscles, persisted after reduction. This state of things indicated injury to the circumflex nerve which, as is well known, encircles the neck of the humerus close to the head and would, it seems probably, be liable to severe stretching in cases where the humeral moves far inward (subclavicular). The method of extension at or above a right angle to the body is attended with danger of injury to the brachial plexus and axillary artery.

At three weeks two successful cases are reported.

At four weeks two cases are reported, in which manipulative methods succeeded.

At five weeks four cases, all successful.

At six weeks two successful cases, and one unsuccessful, the later being a patient of seventy-two years. The patient came into the hospital with edema of the hand, great limitation of motion and much pain, and left in the same condition.

At nine weeks one case was not reduced by manipulative methods. The patient was sixty-four years of age and had fair use of his arm. Manipulation was desisted from owing to the difficulty and danger of further attempts.

At three months there are two cases, in both of which complete reduction was not attained, though the head of the bone was in better position than before operation.

At four months one case is reported. "Head of bone could not be replaced in the socket."

These cases in which, as shown by the fact that the head of the bone was freed from adhesions and brought to the edge of the glenoid, but could not be slipped in, illustrate well the effect of the filling up of the glenoid cavity and closure of the rent in the capsule which has been alluded to above.

At five and a half months we find a case reported of a sailor who fell from aloft on shipboard, and in whom several attempts at reduction made at various times had been unsuccessful. In attempt at reduction, rotation, very moderate in force, was attended by fracture of lower part of body of scapula, and fracture of surgical neck of humerus. The danger of rotation, using the forearm as a lever, has been commented upon above.

At six months two cases are found, in both of which attempts at reduction were unsuccessful, and in one of which, fracture of the surgical neck of the humerus resulted during the attempts.

At eight months one successful and one unsuccessful case are reported, the former being the case of Dr. Burrell alluded to above.

At ten months we find one case, in which Dr. Geo. H. Monks resected the head of the humerus for pain, paralysis and atrophy of the muscles about the shoulder and of all the muscles supplied by the median and ulnar nerves. The man had absolutely no use of his arm. The operation resulted in great improvement of his condition.

At one year there is one case, in which attempts at reduction by manipulation were desisted from on account of fear of fracture.

At one and a half years we have one case, in which Dr. Burrell resected the capsule for a recurrent dislocation on a man of twenty-seven with good result.

A tabular view of the cases, arranged according to time, follows:

Time.	Cases.	Successful.	Failures.	Remarks.
2 to 3 weeks.	4	4	0	
3 "	2	2	0	
4 "	2	2	0	
5 "	4	4	0	
6 "	2	1	1	
9 "	1	0	1	
3 months.	2	0	2	
4 "	1	0	1	
5½ "	1	0	1	Fracture of surgical neck.
6 "	2	0	2	One fracture of surgical neck.
8 "	1	1	0	
10 "	1	0	1	Resection of head of humerus.
1½ years.	1	0	1	Open incision and resection of capsule.
	24	14	10	

A glance at this table shows that all the cases reduced by manipulation were of six weeks' duration, with one exception—that reduced by Dr. Burrell at eight months.

There were 14 successful cases, 13 of them under six weeks. There was one failure at six weeks.

All the cases over six weeks in duration could not be reduced by manipulation, except in the case above noted. There were thus 10 cases in which manipulation failed, and of these 10 only one was of less than seven weeks' duration. In one of these resection of the head of the humerus was attended by a happy result, and in one, a recurrent case, excision of the capsule was successful.

In two of the unsuccessful cases, one at five and a half and one at six months, fracture of the surgical neck resulted from attempts at reduction by manipulation.

If these cases show anything, it is that after more than six weeks have elapsed, such changes have usually taken place as to render success with such manipulative methods as it is safe to employ without danger of fracture of the humerus or rupture of the axillary artery, improbable.

If reduction is to be effected at all, it must be ac-

complished by arthrotomy, with or without resection of the head of the humerus. Whether such operative interference should be adopted, must be decided upon the merits of each individual case. We must be guided by—

- (1) The extent of the present disability.
- (2) The amount of pain.
- (3) The pressure symptoms.

Where very great disability involving inability to earn a livelihood, pain, or paralysis from pressure are present, in dislocations of over six weeks' standing and in patients who are in good condition to bear operation, operative relief should be considered, although both operations are of such severity that the question of their performance should be carefully weighed in each case.

The results of arthrotomy and resection in the last six years give us somewhat greater hope of affording relief to our patients by their employment than those reported in Kocher's and Brun's papers.

The mortality of operative procedures will probably be low if cases in which senile or other constitutional defects render operation dangerous are rigidly excluded, and if in cases where arthrotomy is attempted, and the conditions found point to a difficult and tedious operation, prompt resection is performed.

STERILITY IN THE MALE.¹

BY JOHN G. BLAKE, M.D.

THE rare mention in current medical literature of this subject is the chief reason for this paper. A short summary of the views of writers may not be out of place, and the report of two cases of a rare form of the affection may have some interest for gynecologists.

Sterility in the male is that condition in which, if there be any seminal fluid at all, it lacks all fecundating power. The absence of this power may be dependent upon one or two conditions, namely: the semen may be ejaculated in normal amount, but the spermatozoa are either entirely absent or dead when discharged. This constitutes the condition of azoöspemia. Or there may be a total absence of all seminal fluid, constituting what is known as aspermia. In both cases the act of copulation may be complete. As a corollary to the above two conditions, we might mention malemission, the condition in which the semen is discharged into the male urethra, but is not ejaculated into the vagina.

¹ This paper will appear in the Boston City Hospital Medical and Surgical Reports, Eighth Series.

First of all we will discuss the condition known as azoöspemia, or the ejaculation of semen in which the spermatozoa are either dead or absent when discharged. This condition may be due (1) to failure of the testicles to produce spermatozoa, or (2) to mechanical obstruction in some part of the passage by which the spermatozoa reach the urethra. The testicles fail to secrete spermatozoa when there is a bilateral retention or a bilateral atrophy, or malignant, syphilitic, or tubercular degeneration of both glands. It is also obvious that no spermatozoa will be secreted when both testicles are absent either congenitally or from castration. Occlusion of any part of the excretory ducts may be either congenital or acquired. The latter is the more common; and of the acquired forms, bilateral gonorrheal epididymitis is by far the most common. Among the rarer causes we may mention wounds, syphilitic and tubercular degenerations, and pressure of tumors, whether benign or malignant.

Aspermia is that condition in which either no semen is produced, or it is entirely retained in the seminal vesicles, and no ejaculation takes place. The latter condition occurs only when there is an occlusion of the common ejaculatory ducts, and would not be produced by obstruction of the vasa deferentia. Occlusion of the common ejaculatory ducts is usually caused by posterior urethritis, but it may be congenital, or be caused by traumatism (chiefly that inflicted by surgeons in operating for stone. Concretions are a very rare cause of obstruction of the ducts. The forms of obstruction mentioned above produce, it is true, an apparent condition of aspermia; but, strictly speaking, it is not true aspermia, for semen is produced, although it is retained in the vesicles or in the ducts.

True aspermia is a much rarer condition, and may be due to anesthesia of the *glands penis*, whereby there is no reflex excitation of the ejaculatory centre in the cord. Occasionally anorchides, while incapable of procreation, nevertheless have sexual desire, and occasional involuntary emissions, and are quite able to copulate.

Malemission is where — although testicles and accessory sexual glands secrete normal seminal fluid, capable of fecundating — the fluid is not properly ejaculated into the vagina, but is retained in the male urethra, and exudes drop by drop after coitus has been completed; or the power of ejaculation may be perfect, but owing to some fault in the urethra, such as hypospadias, epispadias, or fistula, the semen escapes from the urethra before it reaches the vagina. The patient suffering from this condition cannot be said to be sterile, neither is he impotent, yet the result is the same; he is incapable of procreation. In view of the fact that about one woman in eight is barren, and that the proportion of sterile men is about the same, it becomes a matter of considerable importance for the physician to decide in which, the husband or wife, the trouble lies. It is usually the young wife who comes to the physician on account of barrenness. The husband is not apt to be as sensitive on this point, since it means a great deal more to the woman. The semen, if there is any, should be thoroughly examined for living spermatozoa. This should be done under the microscope soon after it has been passed. If the spermatozoa are found to be alive, of course the man is potent and we must examine the woman more thoroughly. This applies to cases where the semen is ejaculated normally. Of course the semen,

while it is perfectly normal, may nevertheless, never reach the vagina. Sterility in the male has been confounded with impotence, no distinction having been drawn between the inability to procreate and incapacity for sexual intercourse.

Among gynecologists no inconsiderable number of the cases they are called upon to treat are for the cure of sterility in the female. And many times only failure attends the efforts, when from all appearances and results of local successful treatment the opposite should follow. In a general way, of course, we are aware that from many causes, congenital and acquired, the failure may be in the male, but the actual demonstration by microscopic examination is not often resorted to. Recently it has come under my observation to have this done, and in two cases the results showed that the fault did not belong to the female. And the curious feature of the cases was that in neither of the two was there the least suspicion that the man was in fault. Both were fine specimens of manhood, with keen sexual appetites, married to perfectly healthy young women.

Number one was a man in the prime of life, six feet high, weighing about 180 pounds, living in the open air most of the time, of temperate habits and correct life, with no hereditary tendencies; brothers and sisters married and fruitful; had been married to a woman a few years his junior, but perfectly healthy and of healthy family, for nine years, yet the woman was never pregnant. She consulted me for sterility. I took her into St. Elizabeth's Hospital, and under ether could detect nothing abnormal in the condition of the pelvic organs. Uterus did appear to be a little spongy, with a possible endometritis. It was dilated, curetted and packed, more with a view of ensuring a pervious canal and healthy endometrium than for any marked evidence of existing disease. When in the course of a couple of weeks she left the hospital I felt very confident that there was no obstruction to conception on her part. She had always been perfectly regular in regard to the menses. I was looking for success as the result of the operation, but it did not come. Month after month passed without interruption of the menses. I finally became convinced that the fault was not on the woman's side. A microscopic examination of the semen made by Dr. W. T. Councilman twice within a month showed an entire absence of spermatozoa in both specimens, much to the husband's surprise. He assured me that he never had had any private disease, gonorrheal or syphilitic, never received any injury, and was not aware of any defect in his organization; always enjoyed married life, vigorous sexually, no malformation or atrophy of organs. His disappointment was keen.

Number two was that of an Italian in the prime of life, married for the second time to a young and perfectly healthy woman ten years his junior. They were devoted to each other, and were very much disappointed that no children came. An examination of the wife showed a small os, but normal uterus. Menstrual function regular and not painful. No ovarian disease. The cervix was dilated and packed with gauze for a week, and afterwards an Outerbridge wire dilator inserted. No result. Some months afterwards cervix again dilated to insure an open and straight canal, but without success. After this it was deemed wise to investigate the husband's case. Before doing so, the second wife of the husband's brother remarked

that it was useless to be treating the wife, as the fault was not with her, but with the husband, and that it was a family peculiarity. She was a second wife, and had never been pregnant. Her husband's first wife, although a healthy young woman, had never been pregnant. My patient's husband's first wife had been a young and healthy Italian woman. She had never been pregnant; and so it ran through the family. Husband claimed to have been free at all times from disease of a specific character, showed no results of previous disease, and was free from malformation of any kind. Microscopic examination of semen showed an entire absence of spermatozoa, as in Case No. 1.

In discussing this subject with gynecologists, I find that some of them insist on investigating the husband's condition, and satisfying themselves that he is all right before submitting the wife to treatment, unless there is manifest disease which would prevent conception. I think this a wise precaution in many cases.

THE PERMANENT OR LATER RESULTS OF FRACTURES OF THE SKULL.¹

BY WILLIAM N. BULLARD, M.D.

THIS paper, which is intended only as a preliminary one, is the result of investigations in regard to the present condition of patients who were formerly in the Boston City Hospital with fracture of the skull. The diagnosis is taken from the hospital records and in most cases was evident.

I will not enlarge on the difficulty of this investigation except to say that it has occupied much of my time personally during portions of the past three years. I have attempted to find each patient, and have not accepted any records except from the patient himself or some person whom I believed fully competent to state his physical condition. Of course, very many persons were sought for who could not be found, and it was unusual when any one was found at the address given when at the hospital.

In undertaking this work I had hoped to be able to throw some light on the question as to whether the future condition of the patient with fractured skull were better with or without operation, and under what circumstances operation was advisable. Unfortunately the statistics obtained are too few to obtain any definite answers to these questions, but they may be of value to us as making a beginning in this direction, as well as in other ways. It seems to me that hitherto our views have been influenced by general considerations and by special conditions rather than by definite knowledge derived from a large number of carefully followed cases.

The number of patients in regard to whom information has been obtained is 70: male adults 44, children 15, female adults 2, children 5; age unknown 4 (3 males and 1 female).

The location of the fractures is as follows:

Base	19
Vertex	48
Frontal region	15, right 11, left 4.
Parietal region	19, " 9, " 10.
Temporal region	5, " 3, " 2.
Occipital region	9, " 6, " 2.
Unknown	5

¹ Read before the Surgical Section of the Suffolk District Medical Society, March 3, 1897.

Operations, that is, trephining or some serious surgical interference, occurred in 15. In 54 there was no operation. In one it is unknown whether there was an operation or not.

The longest time which has elapsed in any case between the time of injury and the time of examination is forty-seven years in one case. The next longest is fifteen. In nine patients the time elapsed was between ten and fifteen years; it was between five and ten years in 24 patients; it was four years in five patients; three years in nine cases; two years in nine cases; one year to eighteen months in eight cases; nine months in two cases; and in two cases the time elapsed was unknown, but it was at least several years.

In estimating the results of fractures of the skull, I have not taken into account the paralyses produced at the time of injury, for these are apt to be obvious, and their duration and severity can usually be determined with some degree of probability before the patient leaves the hospital. (There were noted, however, three cases of hemiplegia.) My object has been rather to draw attention to those symptoms which, while less obvious at first, later interfere with the patient's comfort, or ability to work and earn his living. I wish to consider these both in relation to the patient's condition and also in relation to the method of treatment at the time of injury.

Out of our 70 patients, 37 presented *no* symptoms due to the injury, when examined. Of these one was examined nine months after the injury, three one year after, four at two years after, five at three years after, five between three and five years, ten between five and ten years, and the rest more than ten years after, except for two cases in which the time was unknown, but in each it was several years.

Eight patients presented symptoms which were slight or insignificant.

Eighteen patients presented symptoms which were troublesome, but which would not prevent them from earning their living.

Seven patients presented serious symptoms.

In all the cases with serious symptoms there was mental trouble. I will mention these cases in detail.

CASE I. Male, forty-eight. Had fracture of the base of the skull. No operation. He seems to have been a hard drinker before the accident, but after the injury small amounts of alcohol affected him to an extreme degree, so that he would become so violent that his family were afraid of their lives and were obliged to leave him two or three times. When not under the influence of alcohol he was peculiar; "crazy since the injury." He died six and one-half years after the injury of tuberculosis pulmonum.

CASE II. Male, twenty-six years old when injured. Is now at the State Hospital for Dipso-maniacs at Foxboro; seven years after injury. He had been a hard drinker for some years previous to injury, and has continued to be so since. His mental symptoms are melancholy and hallucinations of sight and hearing. It is extremely doubtful whether they are connected with the injury, which was in the left frontal region. There was no operation.

CASE III. Male, ten years old at time of injury. Fracture in right frontal region. No operation. It is now fifteen years since the injury. He is said by his mother to be peculiar. Is "hasty," and probably at times rather violent. Is not addicted to alcohol,

but if he takes any shows its effects more quickly than natural. Has never been the same since the accident. Has a sister who is insane, and her insanity is attributed to the same accident. Is a plumber and able to work.

CASE IV. Male, fifty. Fracture of left parietal. No operation. Thirteen years after injury. Wife states that he has never been the same since the accident, has been less active minded. Was stupid for a time after leaving the hospital, but gradually improved. No headache, vertigo, deafness or tinnitus. Is at work; is a laborer.

CASE V. Male, fifty-five. Laborer. Fracture of left parietal. No operation. Became childish after accident. Was unable to work for a year, and died three years after injury of chronic bronchitis.

CASE VI. Female adult, age unknown. Fracture of base. No operation. After injury her mind was affected, was melancholic, and would sit all day doing nothing. This person was probably alcoholic.

CASE VII. Male, twelve. Fracture of base of skull; hemorrhage from right ear. Eighteen months after injury is slightly deaf; no tinnitus; has headache and dizziness at times. Cannot learn at school since the injury.

The symptoms in the second of these cases are undoubtedly due to alcohol, and those in the fifth and sixth probably so, at least in part. In the third case there is an undue excitability of moderate severity, while in the fourth and seventh we find the opposite, an abnormal mental slowness or stupidity and an inability to learn. In neither of these last two adults (III and IV) were the troubles severe enough to prevent them from working. In the remaining case the patient was said to have become childish.

The only other case where severe symptoms, other than paralysis, were recorded was that of a man seen forty-seven years after a fracture of the right frontal, which had occurred when he was eight years old. He had convulsions daily for a time, but had had only one during the past twelve years. He presented himself at the hospital on account of a posterior sclerosis of the spinal cord not connected with his injury.

The symptoms most frequently found after fracture of the skull in our cases, are, however, headache, vertigo, deafness, and a condition of the brain which shows itself by the extreme susceptibility of the patient to the effects of alcohol. This latter condition is probably present in a large proportion of cases, although not always mentioned.

Headache occurred in twelve, not counting one in which it was noted as rare and another in which it was not common; as a rule, it is not severe or troublesome and does not interfere with work. In two of the cases counted the patients were alcoholic, and it was doubtful how far the injury was the cause of the pain. In three cases the headache was unilateral and on the injured side of the head.

The only case in which the headache was troublesome was that of a man fifty years old at the time of the injury, who had a fracture of the posterior parietal region and of the base. The examination was made fourteen months after injury. He was deaf and troubled with dizziness, and had a constant diffused headache. He was probably alcoholic, so that the cause of the headache was not certain.

In only one of the cases in which headache occurred had an operation been performed, and even in this case

the cause of the headache was doubtful. The injury, which was a fracture of the anterior portion of the left parietal, occurred in a girl six years old. Some fragments of bone were removed and depressed bone elevated immediately after the injury. She was seen nine years later. Her family circumstances had been unfortunate and her inheritance poor. She had been subject to attacks of violent excitement or anger. Three months previous to my visit the headaches had ceased with the appearance of the catamenia.

Dizziness, or vertigo was found in thirteen cases, and in one other it was reported as having existed for two months after leaving the hospital and having then ceased. In three cases it was noted as slight. In one it was unilateral. In two cases it existed in company with tinnitus, and in five cases in company with deafness. Curiously, the tinnitus and deafness were not found in the same cases.

Too much stress cannot be laid on the location of the fractures in cases which are not examined post-mortem, because it is often impossible to determine where the cracks and fissures extend, and it is impossible to exclude other fractures than those noticed.

In the cases of headache, four of the fractures were of the base, four of the frontal and three of the parietal regions, while one was in the region of the posterior fontanelle. Of the doubtful cases one was a fracture of the base, one of the frontal and one of the parietal regions.

In the cases which suffered from vertigo, two of the fractures were in the frontal region, five in the parietal, one in the occipital and six were of the base. In none of these cases had any operation been performed.

Deafness was found in nine cases, in two of which it was noted as slight, and in another it was said to be diminishing. In one case it was bilateral. In four it coexisted with headache and in five with dizziness. In every case where there was deafness and headache there was also vertigo; thus there was only one case in which there was vertigo and deafness without headache. The seat of fracture was at the base or in the bony wall of the ear in six cases; in two it was seen in the occiput and in one the fracture was in the frontal region. As mentioned above, the site of fracture found during life does not show the real extent of the injury. We should naturally expect deafness to occur, principally in fractures of the base, or in such as involved the petrous portion of the temporal bone. In only one of these cases was an operation performed at the time of injury.

Tinnitus was not complained of in any of the cases in which there was deafness. It occurred only twice, and both times in company with dizziness. There was no operation in either of these.

In three cases a sensation of drawing or pulling in the wound was complained of, and this occurred chiefly when the head was in such a position as to cause the brain to sink away from the wound. Two out of the three complained of it especially at night, and said that it kept them awake. This symptom is probably more common than would appear from these statistics. Many of those who have it to a slight degree do not mind it much, and do not speak of it. There was no serious operation in any of these cases: in one some loose bone had been removed.

One of the above cases also complained of a sensation about the wound as if a piece of leather were tacked over it. One patient who had also headache,

complained of a "funny feeling about the head" for some time after the injury, which, when he was seen seven years after the injury, was slight and not troublesome.

In almost all the patients we find an increased susceptibility to the action of *alcohol*, often very noticeable.

CONCLUSIONS.

(1) Out of 70 persons with fractures of the skull, 37 presented no symptoms when examined some time later.

(2) Seven persons only presented serious symptoms, and in at least four of these it is doubtful whether the symptoms were due to the injury.

(3) The most frequent consequences found were headache, deafness, dizziness, and inability to resist the action of alcohol on the brain.

(4) Out of the 15 cases in which operation (trephining, etc.) was performed, 12 had no symptoms; in another it was doubtful whether the symptoms present were due to the injury; in another the symptoms were slight (headache rare, tension over wound while lying in bed); the other was deaf, but had no other trouble. We are justified, therefore, in concluding, so far as our statistics lead, that those cases in which trephining was performed have shown much better results, as far as the symptoms discussed are concerned, than those in which no operation was performed.

Clinical Department.

CASES OF MALIGNANT ADENOMA OF THE UTERUS, VAGINA AND RECTUM; WITH REMARKS UPON THE SURGERY OF THIS FORM OF MALIGNANT DISEASE.¹

BY MAURICE H. RICHARDSON, M.D.,

Visiting Surgeon to the Massachusetts General Hospital; Assistant Professor of Clinical Surgery, Harvard University.

OPERATIONS, even the most extensive possible, for cancer of the rectum and uterus are followed so frequently by hopeless recurrence that they must always be undertaken with reluctance and misgivings. When, however, the disease is of those less malignant types which are slow to invade remote structures the prognosis after thorough removal is so bright that even the most extensive mutilations are justifiable.

The malignant adenomata of the uterus, for example, present after thorough removal the most encouraging outlook. I recall several cases of this disease in which hysterectomy was performed long before the growth had penetrated from the mucous surface of the fundus, where it had originated, to the peritoneum. In these cases there was no return of the growth. It was only when the disease had already invaded contiguous structures that extirpation of the uterus was followed by a fatal recurrence. In cases of malignant adenoma of the rectum also, thorough extirpation has been followed in my experience by permanent cure. In such cases the recurrence, if any takes place, is localized, and the progress slow.

Whatever the views of the pathologists may be as to the course of the so-called malignant adenomata, clinical experience seems to indicate a prognosis much more hopeful than that of ordinary cancer. I recall

one case in particular which has encouraged me, even under the most unfavorable conditions, to remove the uterus when the diagnosis of malignant adenoma of the uterus had been made.

CASE I. Mrs. W. H. K., aged forty years, a patient of Dr. Andrews of Gardner, Mass., was married at nineteen. She had been as well as the average girl. After her second confinement, from which she got up very slowly, she began to have excessive flowing at the menstrual periods. The periods themselves became more frequent, and the exsanguination finally was extreme. On April 26, 1894, I found the patient greatly emaciated and anemic. The uterus was filled with a friable bleeding mass, which I removed as thoroughly as possible by means of a curette. Dr. Whitney pronounced the scrapings to be fragments of a malignant adenoma. On May 17, 1894, I removed the uterus through the abdomen. The fundus was filled with masses of the disease, which had not, however, penetrated to the peritoneum. At the operation no evidence of metastasis was found. A good recovery followed. In the first sixteen weeks she gained sixteen and a half pounds. On February 6, 1897, I saw the patient in perfect health.

Dr. Whitney's report is as follows:

HARVARD MEDICAL SCHOOL,
May 16, 1894.

DEAR DOCTOR:—The examination of the uterus from the case of Mrs. K. showed a large infiltrating growth ulcerating on the surface, with slightly raised, fungous edges. This occupied the cervical region, which was elongated and hypertrophied.

Microscopic examination showed the same characteristic as the scrapings, namely, irregularly shaped glands infiltrating the tissues. The limit between the growth and sound tissue is much sharper than in the cases of a similar character which have had their origin in the fundus of the uterus.

The diagnosis is a malignant adenoma starting from the cervical glands.

Yours very truly,

W. F. WHITNEY.

CASE II. A case of malignant adenoma of the rectum, that of Mr. J. A. R., aged forty-seven, pursued also a favorable course. This man, a jeweller, came to me November 22, 1890. He had had, in the preceding September, without apparent cause, an excessive hemorrhage from the rectum, accompanied by attacks of fainting. On October 19th he had another hemorrhage. He had been troubled for four or five years with constant diarrhea, accompanied by pain dating from service in the war. I found an ulcerated tumor situated in the posterior wall of the rectum, about two inches above the anus. The first operation, that of curetting and burning, was performed in 1890. On February 17, 1891, I removed the mass thoroughly through the dilated anus. Dr. Whitney pronounced the disease a malignant adenoma of the rectum, and gave a hopeful prognosis. In November, 1895, I saw the patient at his place of business in Amherst. He reported himself as perfectly well, and his looks confirmed his statement.

CASE III. Encouraged by cases like the preceding, I advised operation in the case of Miss L. M., aged forty, who had had for about a year some internal trouble which she thought to be connected with the uterus. She consulted Dr. — who found a small growth in the left side of the vagina near the cervix. This tumor was removed by Dr. — on December 11, 1894. It was pronounced a malignant adenoma

¹ Read before the Obstetrical Society of Boston, January 19, 1897.

by Dr. Whitney. On December 9, 1895, she consulted me, after having been told by several physicians that nothing further could be done, a local recurrence having taken place. I found an induration, about the size of a silver quarter, at the seat of the former operation. It could be felt through the rectum, and extended nearly to the cervix. In view of the microscopic diagnosis, it seemed to me possible to attempt extirpation, though such a procedure would evidently require an extensive dissection involving the rectum, the vagina, the peritoneum, and probably the uterus. Such was the magnitude of this operation that I hesitated a long time before undertaking it. The patient was sent to 38 Commonwealth Avenue for observation. She was examined under ether, and an abdominal section was made to see if the growth could be removed by the abdominal route. No indication of the tumor could be found by careful examination with the patient in the Trendelenburg position. Adhesions were evident in the posterior cul-de-sac. An examination of the rectum was made later by Dr. Otis, who reported that the disease did not appear to involve the mucous membrane of the rectum.

It was finally determined to attempt extirpation by an incision through the buttock after the manner of the Kraske operation. On February 6, 1896, a long cut was made through the gluteal muscles, extending from the posterior superior spinous process of the ilium nearly to the anus. The rectum and vagina were exposed by thorough dissection. It was found impossible to remove the mass without opening the rectum as well as into the vagina. The disease extended also into the pericervical space to the left of the uterus. A clean cut was made about the whole mass by means of scissors. A large portion of the cervix was removed, half the circumference of the vagina, and the greater portion of that of the rectum. The peritoneal cavity was widely opened. The open ends of the rectum were inverted and sewed together with interrupted sutures of silk. The wound was then packed tightly with iodoform gauze. The patient was in considerable shock as the result of the operation, which was an unusually long one, lasting nearly two hours. She made a good recovery, however, from its immediate effects. For a long time there was an abundant discharge of feces from the wound. This discharge finally ceased, and she left the hospital well March 21, 1896.

It is, of course, much too soon to assume that in this case the operation is permanently successful: yet in a letter from Miss M., dated September 7, 1896, she reports herself as feeling perfectly well. In view of the extensive operation in this case, and of the merely local malignancy of this form of tumor, it seems reasonable to expect a permanent cure.

CASE IV. Mrs. C. R., forty-eight years of age, living in Waltham, had had three children. The family history was good, except that one sister died of cancer of the breast. This patient had been under the observation of her physician, Dr. McColleston, for about six months. She had in the first place a granular and everted cervix. This healed over under treatment, and she was supposed to be rid of the disease. Nevertheless, she complained of feeling not as well as usual: her digestion was out of order. Soon she began to have attacks of flowing that would last as long as two weeks. There had been some irregularity of the menstruation before. The hemorrhage became exces-

sive. I found the uterus strongly anteflexed and movable, and the cervix indurated and ulcerated. The vaginal wall was not implicated. No metastasis could be found. On April 4, 1894, I removed this uterus at the Waltham Hospital. The patient made a very good recovery, and has been perfectly well ever since. Dr. Whitney's report is as follows:

SEARS LABORATORY,
HARVARD MEDICAL SCHOOL, April 6, 1894.

DEAR DOCTOR:—The uterus from the case at Waltham measured about seven centimetres in length. The fundus was enlarged by a new growth, soft, opaque, whitish, and more or less fungous in character. This growth projected into the uterine cavity and infiltrated the muscular tissue.

Microscopic examination showed it to be composed of large, irregular, tubular glands infiltrating between the bundles of muscular fibres.

The diagnosis is malignant adenoma.

Yours very truly,
W. F. WHITNEY.

The immediate results in extirpation of the uterus for ordinary cancer of the cervix have been in my experience very encouraging; in a considerable number of vaginal hysterectomies I have lost but one case. In many, however, the recurrences have been early, although several patients are now living and free from disease. Still I have no doubt, that my cases of carcinoma have the same deplorable percentage of recurrences that have been observed by most operators. When the diagnosis of malignant adenoma has been made, however, there have been no recurrences whatever that I have been able to find, with the single exception of a case in which at the time of operation the disease was found already to have escaped from the uterus into the intestine. The woman had a recurrence at the end of a year, and has just died. I felt in this case that had the operation been performed sooner a perfect cure would have resulted. Operation had been advised some years before by the attending physician. The patient declined, however, to have any operative interference.

CASE OF SUPPURATING FIBROID TUMOR OF THE UTERUS.¹

BY JAMES R. CHADWICK, M.D.

On December 16, 1896, I was summoned to see a patient of Dr. S. C. Morrill, of Concord, N. H. She was a widow, sixty years of age, of extremely nervous temperament, the mother of several children. She had had an interstitial fibroid tumor of the uterine body, which since the menopause had gradually decreased in size and for many years had given rise to no symptoms. In August she had a distressing domestic difficulty which affected her seriously. Early in September she went to visit friends in Walpole, N. H., where after a long drive she had a severe chill, which was repeated often in the following four months, her temperature varying most of the time from 99° to 103° once rising to 104.5°. Nausea, emaciation to the extent of sixty pounds, and extreme nervousness were the only other symptoms. At no time had there been the slightest tenderness of, or discomfort in the fibroid uterus. Malaria, which is somewhat prevalent in and about Walpole, was suspected to be the cause of her

¹ Read before the Obstetrical Society of Boston, January 19, 1897.

fever, but no definite diagnosis could be made. About December 6th inodorous pus began to escape from the os uteri.

When I saw her on December 16th, the abdomen was filled with a uniformly rounded and hard tumor, manifestly a uterine fibroid. It was freely movable in the abdomen; was neither tender nor the seat of pain or even discomfort. From the os uteri was flowing a small but steady stream of purulent fluid devoid of odor. A specimen of this, submitted to Dr. Mallory on the next day, was pronounced to be pus, and found to contain streptococci pyogenes but no putrefactive bodies. The only two cases of sloughing interstitial fibroid that I had ever seen in my practice followed the use of Apostoli's method of electrolysis (without puncture of the tumor) in the hands of other practitioners. In both, besides continuous fever, there had been pain in, and tenderness of, the tumor, followed by the discharge of a most offensive pus. With these cases in mind I was slow to reach the conclusion that the tumor was disintegrating, so that I resorted to intra-uterine injections of a solution of permanganate of potash. As this treatment failed to have the slightest effect upon the fever, which ranged from 101° to 103° F., or upon the amount of pus discharged, on December 23d I removed the supra-vaginal uterus and the tumor by abdominal section, with the assistance of Dr. G. J. Engelmann, of Boston, and Dr. Wallace Russell, of Concord. The operation was simple and eminently successful, except that, in spite of precautions, a little pus from the tumor dropped upon the lower angle of the abdominal incision. Not a drachm of blood was lost. The peritoneum was brought together over the stump. There was no shock; the temperature fell at once two or three degrees.

The muscular wall of the abdomen healed by first intention throughout, but the lower half of the integument had been infected and is healing slowly by granulation. From the vagina the stump was also infected and pus began to escape from the os uteri about January 10th. As this opening did not seem to drain the abscess fully, on January 15th I made an incision from the vagina into the bottom of Douglas's pouch and washed out the cavity of the abscess.

The tumor, which weighed from four to five pounds, was submitted to Dr. Mallory, who made the following report:

Specimen consists of a spherical mass, sixteen centimetres in diameter, composed of the uterus, with tubes and ovaries, and a large dense tumor mass situated in the anterior wall of the uterus. Cavity of uterus much dilated. Portion of uterus connected with specimen measured thirteen centimetres long, seven centimetres wide. Ovaries small and scarred, and tubes slender.

In the anterior surface of uterine mucous membrane was a small opening, from which pus could be squeezed; a probe could be thrust into the opening two centimetres.

Section through the tumor's mass showed a spherical growth, with a regular grayish-white surface. Scattered here and there were small, irregular, opaque, yellow, dense areas, and also numerous small pockets of thick pus. In the lower anterior portion of tumor was a cavity containing a yellow, irregular, dense, oval mass, five centimetres in length, attached only at one side. Opening off from this large cavity were numerous large and small irregular cavities and sinuses running in all directions, but usually near the border between the tumor and investing uterine wall. Many of the smaller cavities and sinuses still contain pus.

Diagnosis.—Fibro-myoma, with necrosis and secondary infection with streptococcus pyogenes.

NOTE.—After the last report Mrs. B. progressed favorably as to local conditions. The abdominal wound nearly healed, and the pus almost ceased to come from the vagina; but evidences of septic infection became marked, and finally the kidneys became infected and brought about a fatal result about the middle of February, two months after the operation.

A CASE OF SUPPURATING FIBROID TUMOR OF THE UTERUS.³

Dr. C. M. GREEN referred to a case of large fibroid tumor he had seen one month after childbirth. There was a very foul odor present, and a large sloughing mass presented at the vulva. The fundus extended nearly to the umbilicus. After washing out the uterus thoroughly, he passed his hand into the uterus under ether, and found the tumor attached at the fundus. The mass itself which had dilated the cervix was larger than a fetal head. After cutting away the tumor with scissors, the uterus contracted rapidly, and on the tenth day it measured only three and one-half inches. The tumor was apparently an interstitial fibroid that had become polypoid, sloughing taking place from the cutting off of the circulation.

Dr. G. J. ENGELMANN said that the case reported was unusual on account of the lack of symptoms and the discharge of pus for so long a time. Cases of fibroid tumors, treated by electricity, that suppurate he considers do so not on account of the electricity but from septic instrumentation. Martiu has found out of 300 fibroid tumors about one-half undergoing degeneration, and he believes that cystic degeneration is furthered by the electric current, but that suppuration is due to direct infection.

Dr. G. H. WASHBURN spoke of a multiple fibroid tumor in a woman of fifty years where one of the masses suppurated and discharged through the uterus. There was apparently no history of infection. A radical operation being refused, he curetted. Later a second mass suppurated and all operation being refused, the patient died later of sepsis.

Dr. J. R. CHADWICK, in closing, said that he was much surprised that with suppuration going on for four months, with a temperature extending to 103° or 104°, that there should have been no pain or tenderness, and that the pus was not offensive.

Dr. MAURICE H. RICHARDSON read a paper entitled

³ See page 407 of the Journal.

REMARKS UPON THE SURGERY OF THE MALIGNANT ADENOMATA, WITH ILLUSTRATIVE CASES.¹

DR. J. R. CHADWICK referred to a case of malignant adenoma of the uterus that lasted for twenty years with frequent curetting. Ten years ago he took out the organ, and the disease has not recurred.

DR. W. E. BOARDMAN said he had a case of this affection under his care twenty years ago, when the patient died notwithstanding curetting. Soon after this he had another case where the diagnosis of malignant adenoma in its initial stage was made. The patient lived six years with the help of curetting. At that time he felt sure that if the uterus were removed the disease would be easily and completely cured.

DR. M. H. RICHARDSON, in closing, said that malignant adenoma was more circumscribed than ordinary cancer; it was more fungous in its growth and bled more easily. In the rectum it was more distinct and movable than ordinary cancer.

Clinical experience does not bear out the great malignancy as reported by some pathologists, although all do not agree on this point. The question is properly raised whether successful cases of removal of the uterus for cancer are not of this variety. When the disease starts, it grows slowly in the glands of the uterus, but when it reaches the surface its growth is rapid.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

PAUL THORNDIKE, M.D., SECRETARY.

REGULAR Meeting, Wednesday, February 3, 1897, DR. H. L. BURRELL in the chair. Dr. Burrell invited DR. PADDOCK, ex-President of the Massachusetts Medical Society, to preside.

DR. F. B. LUND read a paper on

THE TREATMENT OF OLD DISLOCATIONS OF THE SHOULDER-JOINT.¹

Dr. Lund showed a patient to illustrate the subject of dislocation.

This patient dislocated his left shoulder fifteen years ago, and was given some medicine by his physician, which he says brought his shoulder gradually back into place. It is easy to see that the head of the humerus is under the coracoid process, and the glenoid cavity is empty. The interesting point about the case is the amount of motion the man has, partly owing to the formation of a new socket under the coracoid process, and partly to the participation of the scapula. As you will see, all movements are normal, except that rotation is slightly limited, and he cannot raise the arm to a perpendicular without swinging it slightly forward of the median plane of the body. He can, however, touch the back of his head, put his hand behind him, and perform all these motions without pain. He has for practical purposes, a normal arm, and no one would think for a moment of operating on his old dislocation.

The man, who is fifty-three years old, and subject to occasional epileptic attacks, entered the Boston City Hospital (in the service of Dr. H. W. Cushing,

¹ See page 397 of the Journal.

² See page 406 of the Journal.

who has kindly allowed me to present him) a few weeks ago for fracture of the surgical neck of the right humerus, with subcoracoid dislocation of the head, which was irreducible. In view of the excellent use he has of his other arm, and of his poor physical condition, it was thought best by Dr. Cushing not to attempt operation, but to dress the arm, allow the fracture to heal, and then begin manipulation with a view to establishing a new joint in the present position of the head of the bone. In view of all the conditions, it would seem that this is the wisest course in this case.

DR. PORTER: The paper of Dr. Lund has covered the ground so thoroughly that it does not leave a great deal but that of personal experience to supplement what he has said. It is true that old dislocations of the humerus present a difficult question for the surgeon. Writers have usually considered that dislocations after three months should be considered old dislocations. Dr. Lund's paper by statistics apparently establishes that after six weeks they must be considered old dislocations. Nevertheless, many instances of success in reduction have been reported at longer periods than three months. In the manipulative measures for breaking up adhesions great care must be used in order not to injure the vessels, as Dr. Lund has brought out, and especially when that force is directed upwards and when there is tension of the vessels over the head of the humerus. It would seem to me that in all cases of old dislocation attempts at reduction should be made, and that the length and violence of the attempt should be determined by the age of the patient, by the firmness of the adhesions, and by the amount of disability and pain. We have had shown just now a case where there is very little disability and no pain, and where the man has a good result without any reduction of the dislocation. It is not, I think, a fact that the length of time in all cases is the important factor. The kind of injury—the amount of injury at the time of the dislocation—determines to a large extent, I think, the denseness, the firmness of the adhesions. Where there is attachment of the axillary vessels or the nerves to the head of the bone, which is considered as one of the important reasons for not using violent attempts at reduction, it seems to me that if rotation is made, partial rotation, and the radial artery is affected in the pulsation, it might be a means of diagnosing as to whether the artery is involved in the adhesions; and the amount of pain or the amount of paresis or paralysis might indicate to a certain extent the involvement of the nerves. I made the statement that after longer periods than three months old dislocations had been reduced. I have the records of a case in which reduction was accomplished four years after the injury.

A number of cases are reported where there was rupture of the axillary artery and where ligation of the two ends of the artery was made, several cases where the subclavian was tied, and yet they have resulted fatally. I think, however, that nearly all those cases were cases operated on before our present methods of wound treatment; and now I think that such a class of cases should be approached with a much greater feeling of possible benefit to the patient than in the times when we were sure to have such things followed by suppuration. One of my own fatal cases was long ago, where a young man suffered so from pain that he was willing to have anything done to re-

lieve him from pain. It was impossible to reduce, and I cut down and exsected the head of the bone, and he died some time afterwards from sepsis and secondary hemorrhage.

The fracture of the bone or of the neck in reduction is, I should say, one of the methods of cure. It is not an ideal one; but I had a case of that kind years ago when I was dispensary physician where I fractured the head of the humerus in attempting reduction. The fact was entirely concealed from the patient, and he made an uninterrupted recovery. He was a builder, and before that time he was unable to climb a ladder; afterward he resumed his old vocation.

Dr. Lund spoke of subcutaneous division of refractory bands, and condemned it most heartily, as I do, as a very blind method. The open section and division of the muscles and the bands would be far preferable, and should always be resorted to in case the patient and the conditions admit operative interference. The section of the surgical neck and persistent passive motion might, as it has already been proved, be of benefit in a certain number of cases, and I am sure there are certain cases where an attempt to dig the bone out of its bed results in putting the patient into a much more serious condition than where there is simply section of the surgical neck. The exsection of the head itself is a really difficult task, and a dangerous task even, when you can see what you are doing as you can in the open method; but if successful, it is effective. If it is to be exsected, it is the safest method to do it subperiosteally, to dig it out from the attachments of the muscles and the periosteum; and in that way injury to the vessels and nerves is certainly avoided. The special indication for the operation is pain or paralysis. This subperiosteal operation is not to my mind the best, because the head forms again and the old pain is likely to return even if it is relieved at the time. I have done the operation subperiosteally and to the very great relief of the patient, and I do not know that the pain has returned, but the new bone has formed in the old place. That had formed to a certain extent before he left the hospital, but he did not complain of pain in certain parts of the hand, of which he complained very much before the operation. I should say with our modern method of treatment of wounds that the best surgical operation was open section if manipulations will not allow of the placing of the bone in the socket.

I asked one of my house-officers to look up the old dislocations at the hospital with these results; but he took all of the cases that were a week old, and from that to ten months. There were 36 cases: 27 reduced, partially reduced one, fracture with dislocation two (that was at the time of the accident), and fracture from the operation three, Kocher's method two, incision and wiring one. I asked to have statistics running from three to ten months: 11 cases, six reduced, five unreduced, and in looking over the list, the oldest one which I have reduced without operative interference was a dislocation into the axilla, adhesions broken up by manipulation, good position and good result at four months after the injury.

DR. J. W. ELLIOT: Dr. Lund has covered the subject entirely I should think, and there is very little for me to say. The only point on which I should differ slightly with him is as to how the force can with the greatest safety be used in breaking up the adhesions. It seems to me it is not so much how as it is the

amount of force. If you have an adhesion to break, it takes a given amount of force to break it. Whether you use leverage or rotation, if you break that adhesion you must use the necessary amount of force. The different ways of using force I do not believe make much difference. Suppose the adhesion was on the radial artery, if you use enough force to tear the artery open it does not make any difference whether you rotate or pry or pull, it is the amount of force. The same would be true in breaking the head of the bone. You can get more force with leverage than by a straight pull. It seems to me it makes very little difference how you use it, except, as Dr. Porter suggests, you must not push against the vessel. The force must correspond to the resistance, and it is a question of judgment as to how much force the bone will stand.

As to the operations, of course we all agree that the only two operations would be open section and replacing the head of the bone or excision. My own experience is that both are extremely difficult operations, and much more difficult than is ordinarily supposed, and much more difficult than I had expected.

One case which I did two years ago resulted fatally. It was an old dislocation, and attempts had been made in the out-patient department at the Massachusetts Hospital to reduce it, with the result of breaking the bone. The bone was broken in such a way that it could not be left as it was. It was a spiral fracture with a rough end. After a good deal of consideration I determined to try to get the head of the bone into place. The operation took me at least two hours. There was a great deal of hemorrhage. I think the bone had been out of place about three months. I found the glenoid cavity was not filled with fibrin but healthy and shiny. The adhesions about the bone and shortening of the muscles were very marked, and toward the end of the operation there was a great deal of venous bleeding, and I packed the wound and put on pressure. Unfortunately the bleeding came on later, and could not be stopped; and I now think (I did not think so then) that probably the axillary vein was ruptured at the time the bone was broken by the attempts to reduce the shoulder. But that experience showed me that the operation of returning the head of the bone is extremely difficult. I happened to see one of Dr. Porter's operations for excision of the head, and that was also extremely difficult. I do not know which was the more difficult. So far as the results go, it seems to me very probable, from what I know about these cases and from the statistics, that the resection of the head of the bone will give the best results, although there is one disadvantage in resecting the head of the bone, and that is, if you take off the head of the bone, you lose the power of rotating the arm, which is quite a serious disadvantage: on the other hand, the section of all the muscles which is necessary in the other operation, as they are almost always shortened in these cases, must usually lead to stiffness about the shoulder, in spite of the case reported by Dr. Porter as having given a good result.

DR. BURRELL: I would like to add just a word in regard to the application of force in reduction of dislocations in the head of the humerus. I have used in two instances what I term "fractional breaking up of the adhesions"; that is, in one case where I thought I had to deal with brittle arteries I was extremely cautious in applying force, and was finally successful in

reducing the dislocation of the head of the humerus at the third sitting, the breaking up of the adhesions being carried out at intervals of ten days. It is a method which I feel sure is applicable in certain selected cases.

DR. PORTER: I want to put a little more emphasis upon the great difficulty of removing the head of the bone when it is out of its place. I have done a number of cases now, and I have been impressed each time before I had finished with the difficulty of the operation; and I am sure it is not an exaggeration to say that it is an extremely difficult and certainly a dangerous operation.

DR. LUND: There is very little for me to say. I should agree with Dr. Porter that the cases of ruptured artery which have been so uniformly fatal have been mostly reported from the pre-antiseptic period. I was surprised to find how few cases had been reduced after six weeks, and if I had carried my investigation farther, I doubtless would have found certain cases reduced after longer periods, as I found Dr. Burrell's case at eight months, and Dr. Cushing has since told me of a case reduced at three or four months. I think that these statistics, although incomplete, are enough to show that in the joint which has been out six weeks changes have taken place which render reduction extremely difficult. I have never seen an account of the head of the bone forming after resection has been done. It would seem improbable that enough bone would form to take the place of the large globular head of the humerus which has been removed. As Dr. Elliott has said, resection of the head of the bone has the disadvantage of destroying the power of rotation. He speaks of the muscles being shortened. The posterior rotators instead of being shortened will be lengthened, as they are stretched over the glenoid cavity and carried in front so that their shortening would not make much difference. The subscapularis muscle, however, would be very much shortened from the deformity which takes place in dissection.

I showed from the statistics that resection of the head of the bone had a greater mortality than arthrotomy. From Dr. Porter's remarks it is evident that probably resection is nearly or fully as dangerous an operation as arthrotomy, and not less dangerous, as I had been led to believe from reading the accounts of the recent cases.

REGULAR Meeting, March 3, 1897, DR. H. L. BURRELL in the chair.

DR. W. N. BULLARD read a paper on

THE PERMANENT OR LATER RESULTS OF FRACTURE OF THE SKULL.²

DR. D. W. CHEEVER: I think the first thing that strikes us in this paper is the small number of people who have any symptoms, and the very small number who have serious ones. More than one-half, or quite one-half, have no symptoms; 7 out of the 70 have serious symptoms, or 1 in 10, and more than one-half of these have other causes to which the trouble might be attributed. I notice the word epilepsy, or epileptiform symptoms, is not once mentioned in the report; therefore I conclude there was nothing resembling that, which would attract the attention of an observer so careful as the reader. This, then, would

seem to be quite against our preconceived opinions; and if people can have undoubted fractures of the skull, whether treated or not, and go on for periods varying from a few months to forty odd years without necessarily having epilepsy, and without having symptoms which are severe enough to prevent them from getting their living, or appearing like ordinary people, then that is against our preconceived notions of injuries of the skull. We had supposed that slight depressions, irregularities on the inner surface of the skull, moderate degrees of adhesion of the meninges, slight thickening of the meninges, developed inside of the skull, due to the injury and not to syphilis, were causes of epilepsy. When we trephined for epilepsy we were satisfied if we found some little thing of this kind. In these cases such phenomena, as due to epilepsy, have not been observed. Moreover, these patients are of a class where a great many other causes come in to vitiate statistics, notably, heredity, alcohol and stupidity, native stupidity from want of true education and development. It is quite noticeable, I think, to those who have occasion to go about our public schools how many stupid children there are born of stupid parents; and if these children get an injury to the head, their stupidity may be in a degree ascribed to that, when it was the result of want of intelligence from birth. So that altogether I feel that the statistics do not prove that injuries of the head are necessarily followed in a large percentage of cases by symptoms which call for surgical interference, although as far as the statistics go they do show, that those who have been trephined or operated on were a little better off than the others. Now, what is the objection to interfering and trephining? The objection which existed formerly is gone. Formerly it was fatal. It was found in the first five years of the City Hospital that two thirds of those operated on for fractures of the skull died. Precisely the same mortality occurred in those not operated on, so that the operation of trephining in those first five years was practically a useless operation, and it was looked upon with dread. All that is changed now under the antiseptic methods of treatment; and under improved technique a great many operations are done on the skull which are harmless; portions are sawed out, and pieces taken away, and large trephine holes made, and even new pieces implanted, without producing septic symptoms, or meningitis, or leading to any fatal result; consequently we have greater reason to operate now than formerly provided it will do good.

The reader has said that it is impossible to tell how far these injuries extend. That is notably the case with regard to cracks and fissures of the skull. Given a case of scalp wound in which we push back the flesh and find a crack running through the skull without depression, what are we to do? What are we to gain if we find one end and do not know where the other end is? Moreover, I am personally cognizant of several cases, one a very marked one, in which, over twenty years ago, I was called to a child of an epileptic mother, who had been thrown from a horse, and I found a scalp wound and a crack in the skull, but no depression. My dread of trephining in those times, and fear of doing more harm than good, led me to do nothing. That person grew up; no consequences have followed; inherited epilepsy has not come on, nor has induced epilepsy come on from the injury to the skull.

² See page 404 of the Journal.

There is another class of cases in which we cannot trephine with benefit, and those are the supposed fractures of the base. Some years ago, I published 21 cases where there was marked discharge from the ear, and 12 of those recovered, indicating that if there was fracture of the base it was recovered from; and indicating that discharge from the ear did not necessarily prove that fracture of the base had extended any farther than through the middle ear.

What can we do by trephining in fracture of the base? We cannot get at the seat of the mischief in the bone. Now I would not be considered as wishing to say that in these times when we can trephine safely we should interfere less than formerly, because I believe there are a great many cases where interference does good; but I would say in connection with these statistics, that the analysis of the 70 cases does not prove that the cases let alone did much worse than those interfered with. Trephining is indicated in all punctured fractures where the outer plate is cracked, but the inner plate is splintered and loose fragments are lying on the meninges. Trephining is indicated in every case with depressed fracture, in any case where we have symptoms of compression sufficiently localized to make us think we can reach a piece of bone or clot or anything of that kind. In these cases it is a safe operation, a useful one, and no doubt always will be done; but in cracks, and in a fracture of the base, in many cases, I think, we shall be able to get along without it. No harm can ensue, that I can see now, under antiseptic methods, in any case of supposed head injury, in exploring down to the bone, by cutting through the scalp; I should be a strong advocate for that. The diagnosis having been established that depression does not exist, and other symptoms having established that compression does not exist, in these cases I should be inclined to let the patient alone.

I wish to pay a tribute to the writer for the very laborious efforts he has made in preparing this paper. This paper embodies four years' work—four years of research, and under the most discouraging circumstances. It is the true and only way we can get at facts; and if we had more of this sort of investigation going on, in time we should get something on which we could base a mature judgment. If I may be allowed to quote some sentences written in 1860:

"The study and analysis of phenomena, and their relationships, and not the discovery of any general law like gravitation, marks those who are the Newtons of medicine. The science of medicine wants facts; comparable, numerous, well observed, carefully arranged, minutely classified, and acutely analyzed. But little reward awaits those who collect them. He who devotes himself to the science of medicine must expect little sympathy from the mere votary of the art. His reward lies in posterity, and the test of his conclusions must be in the future. No other agent but the lapse of time can rightly estimate the varied elements which constitute the science and the art of medicine. This alone can finally arbitrate between the claims of statistics and of the other methods of observation."

DR. WATSON: I have but little to add to what Dr. Cheever has just said, but should like to echo his tribute to Dr. Bullard for the admirable work that he has done in this department of surgery. The surgeons of the City Hospital are the only ones who realize its ex-

tent and all the labor that it has involved for him. And we who have derived so much benefit from its results, have much to thank him for.

As Dr. Bullard has said of his paper to-night, it contains insufficient data to rest a final judgment upon with regard to the ultimate results in patients who have been operated on, as compared with those who have not, and I cannot speak with any authority upon this aspect of the subject, and must confine myself to a word or two with regard to the immediate results.

I venture to differ with Dr. Cheever in his scepticism—if I understood him correctly—as to the value of trephining in cases of fracture of the base, for it does not seem to me to accord with our present experience, which records numerous examples of the saving of life by this means, and, so far as can be judged, of permanent recovery of the patients. Among these are some in which there can have been no doubt as to their inevitably fatal issue if left without operation.

I will only mention one of three or four striking instances that occur to me as an illustration of the advantages of trephining in fractures of the base. Dr. Bullard and I went to the hospital three years ago, and found a man who had been injured about seven hours before. There was a fracture beginning near the parietal eminence and extending forward through the frontal bone and the orbital plate, backward as far as the sella turcica and downward and laterally as far as the petrous portion of the temporal bone. The middle meningeal artery was ruptured, and also the cavernous sinus. There was a very large clot. The patient, when I had removed bone enough to sweep out this clot, was very nearly dead. Within a few seconds after removing the clot the respiration became normal, the pulse was restored, and the patient went on to recovery, as Dr. Cheever will remember, as he had the arduous task of pulling out three or four feet of iodoform gauze from beneath the brain. I saw him eighteen months after the operation, practically speaking perfectly well. I think that a good many of us who have had successful instances of trephining for fractures of the base, would not quite agree with Dr. Cheever's view; but I express this with some hesitation, in view of his far greater experience.

DR. BULLARD: I have only two things to say. One is in regard to the question of the certainty of the diagnosis. In the majority of the cases the fracture was seen at the hospital. Most of these cases were compound fractures, and the fracture was seen through the wound, so that the diagnosis was pretty certain. The question of epilepsy has been raised by Dr. Cheever. Convulsions were inquired about in every case, and I think we may say there were none, at least in the majority of cases. Convulsions are a symptom one would scarcely neglect to notice unless they come on at night, and I think we can fairly conclude that 69 of the cases did not have convulsions; the seventieth case did have them. He was a man who was injured when eight years old, seen forty-seven years later. He had convulsions daily for a time, probably epileptic in character; but these convulsions had disappeared as he grew older, and for the past twelve years he had had but one, so that he was practically free from them.

THE PRESIDENT: I believe I voice the feeling of the Section in expressing our thanks for this most admirable paper, and also the hope that Dr. Bullard will continue in this work.

Recent Literature.

The Practice of Medicine. A Text-Book for Practitioners and Students, with Special Reference to Diagnosis and Treatment. By JAMES TYSON, M.D., Professor of Clinical Medicine in the University of Pennsylvania, etc. Illustrated. Philadelphia: P. Blakiston Son & Co. 1896.

Dr. Tyson is no less qualified to write a Practice of Medicine than any of his contemporaries, and they are not a few, who have done the same within recent years. He offers no apology for his act, and does not claim that it was done to fill a long-felt want. He tells us that he had long contemplated such a work and had devoted to it several years of labor. Such a statement at once disarms criticism and invites confidence and appreciation. Dr. Tyson simply did what he had long wanted and intended to do. He has produced a good book on the Practice of Medicine—a text-book, but hardly a hand-book; a quarto, rather than an imperial octavo, of almost 1200 pages. Its pages offer internal evidence that much labor and time have been spent upon it, and as the work of one man it is a creditable monument to industry, learning and good judgment.

The book is divided into fifteen sections. Section I is devoted to the infectious diseases, and the first chapter begins with typhoid fever. The following sections up to XIII, with the exception of Section IX which comprises constitutional but non-infectious diseases, are based upon an anatomical or physiological classification. With Section XII we reach the intoxications; Section XIII deals with exposure to high though bearable temperature; Section XIV, the animal parasites and the conditions caused by them; Section XV, symptoms following overdoses of poisons, their treatment, etc.

Throughout the book both the English and metric Systems are used. The index is full and carefully prepared. The paper is good and the print is distinct and clear. The illustrations, some of which are colored, are well chosen, and the book is not overloaded with them, although the author found it necessary to depart from his original intention of avoiding them altogether.

A Manual of Clinical Diagnosis by Microscopical and Chemical Methods. For Students, Hospital Physicians and Practitioners. By CHARLES E. SIMON, M.D., Late Assistant Resident Physician Johns Hopkins Hospital, Baltimore. In one octavo volume of 504 pages, with 132 engravings and 10 full-page colored plates. Philadelphia and New York: Lea Brothers & Co. 1896.

The author of this work justly dwells upon the great importance in the modern practice of medicine of laboratory methods of diagnosis. The more medicine becomes a true science the more valuable a hand-aid will the laboratory become.

The author's aim has been to present to students and physicians those facts in clinical chemistry and microscopy which are of practical importance. Chemical and microscopic methods are described in such detail as to enable the student and practitioner without special training in the required manipulations to still obtain satisfactory results. Examinations of the blood, the secretions of the mouth, the gastric juice,

feces, nasal secretion, sputum, urine, transudates, exudates, cystic contents, semen, vaginal discharges and milk are described and detailed in the thirteen chapters into which the book is divided.

Dr. Simon's book covers the objects for which it was written very satisfactorily, and will be found useful by those who desire a guide in the department which he elucidates.

A System of Medicine. By many Writers. Edited by THOMAS CLIFFORD ALLBUTT, M.D., LL.D., Regius Professor of Physic in the University of Cambridge, etc. Volume I. New York: Macmillan & Co. 1896.

The editor of this work points out at once, in the introduction to this first volume, that the title chosen is only to be regarded as necessary for present purposes but not as defensible on logical grounds, that a system of medicine cannot now be written by one man or by many, and that this state of things is by no means to be regretted. He is naturally impressed with the vast increase of matter with which such a work to-day has to deal, even over that of the time of the first appearance of the system by Sir Russell Reynolds, to whom this is dedicated. This comparison, though not directly applied by Dr. Allbutt, must probably have been in mind.

To meet in some measure this difficulty, to obtain condensation, to avoid repetitions, to enlarge the conceptions of the student, to lead him to see the domain of medicine from points of advantage by means of broader surveys of general pathology, of statistics, of dietetics and therapeutics, the editor has adopted the incorporation of prolegomena or short introductory articles. The prolegomena in this first volume occupy nearly 500 pages out of a total of 960 pages, and make up Division I of the book. They are on a very considerable variety of subjects by very competent men, and offer a series of medical essays which have no necessary or essential relation to each other, but which are excellent reading. With the 491st page, Division II, the volume gets down to systemic work, and takes up Fevers. Division II is subdivided into two parts, the first of a few pages only on Insolation; the second part, which occupies the rest of the volume, is devoted to the Infections.

We cannot judge from this first volume how convenient Dr. Allbutt's System will prove as a book of reference, but it promises to offer interest and suggestiveness to the reader. There is a double index of authorities and diseases.

Rheumatism: Its Nature, its Pathology and its Successful Treatment. By T. J. MACLAGAN, M.D. Second edition. London: Adam & Charles Black. 1896.

Twenty years elapsed between the introduction of salicin to the notice of the profession by Dr. MacLagan in March, 1876, and the publication of this second edition of his book, the first edition of which appeared in 1881. Dr. MacLagan still holds to the miasmatic theory of rheumatism. Whatever the theory, as a matter of fact we all recognize the specific efficacy of the salicyl compounds in acute rheumatism. The disease has in a great degree lost its interest to the practitioner, and a new edition is changed in so far as it is a record of the continued triumphs of salicylic acid and its congeners.

A System of Practical Medicine. By American authors. Edited by ALFRED LEE LOOMIS, M.D., Late Professor of Pathology and Practical Medicine in the New York University, and WILLIAM GILMAN THOMPSON, M.D., Professor of Materia Medica, Therapeutics and Clinical Medicine in the New York University. To be completed in four imperial octavo volumes, containing from 900 to 1000 pages each, fully illustrated in colors and in black. Vol. I, Infectious Diseases. Philadelphia and New York: Lea Brothers & Co. 1897.

It will not be the fault of the professors in our leading medical schools, or of the medical publishing houses, should any practitioner of medicine find himself unprovided with about the kind of Practice or System of Medicine which he requires. The choice is already great and is rapidly becoming greater. The increasing fruitfulness of investigation into the causes of disease, and the increasing definiteness of modern medicine in its practical applications are the reasons alleged for the preparation of new systems and new encyclopedias, and will probable continue to prevail as ostensible motives, at least, for superseding those already produced.

The present System has been prepared to meet a want. The editorship was originally assumed by the late Dr. Loomis, who associated Dr. Thompson with him. Dr. Loomis before his death had secured the contributors, apportioned their subjects, and decided the arrangement and classification of the work. The authors are all Americans. The design has been to give the system a practical character, to present a work of ready reference for the practitioner of general medicine. General articles have been excluded. The work when completed will have four volumes. This first volume treats of the infectious diseases, and among its contributors appear the names of not a few of our best-known medical writers and teachers.

Twentieth Century Practice. An International Encyclopedia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by THOMAS L. SPEDMAN, M.D., New York City. In Twenty Volumes. Vol. IX, "Diseases of the Digestive Organs." Vol. X, "Diseases of the Nervous System." New York: William Wood & Co. 1897.

Volume IX of this Encyclopedia, which follows Volume X, is practically a continuation of Volume VIII on the "Diseases of the Digestive Organs." The difficulties almost inseparable from an attempt to realize the co-operation of many and widely separated contributors, have probably forced the editor to an arrangement of articles which he would not by preference have adopted.

Mikulicz and Kümmel contributed to Volume VIII an article on diseases of the mouth, which practically dealt only with systemic diseases. In this volume the same writers finish what was there begun, and deal with the local diseases of the mouth. Ewald, of Berlin, than whom no one is more competent, contributes a section on diseases of the intestines, exclusive of infectious diseases, parasites and hernia. Gibney and Walker, of New York, deal with hernia. Stengel, of Philadelphia, treats of diseases of the spleen. Scumola and Gioffredi, of Naples, have been entrusted with the important subject of diseases of the liver, and to it is given 326 out of the 820 pages of this

volume. The last article is on diseases of the gall-bladder, by Dr. John B. Murphy, of Chicago.

It is impossible to criticise at length a series of monographs on a variety of subjects, though all coming in a general way under the one head of "Diseases of the Digestive Organs." It is sufficient to direct attention to the names of the contributors, who are all men of reputation and some of marked distinction. The assignment of subjects was judiciously made, and the treatment of the topics by the writers justifies their selection by the editor.

Volume X is devoted to "Diseases of the Nervous System." With the exception of Dr. Féré, of Paris, who furnishes articles on hysteria, epilepsy, and the spasmodic neuroses, the contributors to this volume are all our own countrymen—the international element is less in evidence than in the preceding volume.

Dr. Joseph Collins, of New York, has a long article of 300 pages on the important subject of diseases of the brain, and another on diseases of the meninges. Dr. B. Sachs, of New York, deals with tumors of the brain, and is sanguine enough to predict even far greater success in the diagnosis and surgical treatment of intra-cranial neoplasms during the next decade than has been achieved in the recent past. Dr. Charles L. Dana, of New York, writes on neurasthenia; Dr. H. T. Pershing, of Denver, on disorders of speech; and Dr. Sanger Brown, of Chicago, closes this volume of 859 pages with a short article on the disorders of sleep.

Artificial Anesthesia. A manual of Anesthetic Agents and their Employment in the Treatment of Disease. By LAWRENCE TURNBULL, M.D., Ph.G., Aural Surgeon to the Jefferson Medical College Hospital, Philadelphia; Late Honorary President to the Otological Section of the British Medical Association, and of the Section of Laryngology and Otology of the American Medical Association. Fourth edition, revised and enlarged, with illustrations. Philadelphia: P. Blakiston, Son & Co. 1896.

In the fourth edition of this well-known and successful book, the subject of anesthesia and anesthetics has been brought up to the present time by the addition of an account of the most important researches and discoveries in this subject during the last six years.

The discussion of the qualities of the most important anesthetics, their advantages, dangers, and methods of administration is very full; and excellent accounts of the symptoms and treatment of collapse under general anesthetics, are to be found.

The subject of resuscitation by the Laborde method of lingual tractions on the tongue is treated more fully than its importance warrants; and, in fact, the chief fault of the book as a practical manual is its loading up with consideration of unimportant and obsolete methods and anesthetics, which instead of being put together at the end of the book, are scattered throughout its whole body, to the confusion of the student who seeks to obtain from the book an idea of the relative utility and importance of the various anesthetics.

The book is better fitted for a reference book for the advanced student of the subject than as a practical manual for the undergraduate in medicine, being characterized rather by exhaustiveness than symmetry of arrangement.

The various methods of local anesthesia receive adequate consideration.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, APRIL 29, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS.

KOCH'S NEW TUBERCULIN.

KOCH has published a long article¹ in which he describes his new and improved tuberculin, towards the preparation of which he has been for several years experimenting. The end sought by all these endeavors in the employment of cultures of tubercle bacilli and their artificial introduction into the animal organism has been the prevention of tuberculosis, or what amounts to the same thing, the obtention of a state of immunity. Immunity to be efficacious must be twofold — against the bacteria and against the toxin — and this complete protection, always difficult of realization, is especially so in respect to tuberculosis. Concerning the difficulties encountered by him in seeking a lymph which would render the human subject immune, Koch found that solutions with dead bacilli caused bad abscesses. All attempts made to cause the absorption of tubercle-bacilli, living or dead, introduced into the subcutaneous cellular tissue, the abdominal cavity or the blood, failed completely. The endeavor by chemical means, as by subjecting the cultures to dilute mineral acids or to strong alkalies, indeed resulted in rendering the bacilli less irritant, but destroyed the immunizing property of the lymph. When he filtered the fluid, it had no better effect than his first tuberculin, the glycerized extract, which has proved so efficacious as a means of diagnosis of tuberculosis, even at so early a stage that clinical observation and physical examination fail to detect the disease.

When after several years of experiments he came to the conviction that the bacilli in an unchanged state could not be absorbed, he sought for means to destroy them mechanically without destroying their characteristic properties, as was done by dissolving them chemically. In former experiments he had found that the bacillus contained two peculiar chemical substances, both of which belong to the class of fatty acids, not saturated. The one is soluble in diluted alcohol and is easily saponified by carbonate of

soda lye, the other only in boiling alcohol or ether, and is not so easily saponified. Both assume the so-called tubercle bacillus tint, and keep this tint after being treated with nitric acid and alcohol. These fatty acids form a connected layer in the body of the bacillus. They protect the bacillus against attacks from the outside and render absorption difficult. The object, therefore, is to destroy this protective envelope, so as to render the tubercle bacilli easily absorbable. All the first experiments failed. Only when well dried cultures were taken and worked about for a long time in an agate mortar without any admixture, it was found that the bacilli decreased in number and that finally only a few remained. In order to get rid of these, Koch diluted the substance thus obtained with distilled water and worked it about by means of a very powerful centrifugal machine which made four thousand revolutions in a minute. The fluid was in about half an hour divided into a whitish, opalescent, but quite transparent upper layer which contained no more bacilli, and a muddy sediment sticking fast to the bottom. The latter was dried again, then worked in the mortar, and by the machine, and was divided as before. This manipulation was continued till nothing remained but a clear fluid.

This experiment was the basis of Koch's further work. At first he convinced himself by experiments on animals and later on human beings that the preparations so gained were all completely resorbable, and never caused abscesses. It was further shown that though the first fluid differed considerably from the others, these were all alike. Koch called the upper layer "Tuberculin O," abbreviated, "T. O.," and the bottom layer "T. R." (tuberculin remainder). Treated with glycerine, T. R. showed that it chiefly contained the ingredients insoluble in glycerine, while T. O. contained those soluble in it. T. O. is very much like the ordinary tuberculin in its qualities. The T. R., however, has a decidedly immunizing effect. It certainly causes some reaction if too large a dose is given, but its effect is quite independent of this reaction. Whilst in using ordinary tuberculin, reaction must be purposely provoked in order to obtain curative effects, Koch says that in using T. R. such reaction should be avoided. For this purpose he tried by gradually increasing the doses which were made to follow each other as quickly as the patient's condition allowed, to make him insusceptible to the effects of a larger dose — that is to say, render him immune to T. R. and against the tubercle bacillus itself. If a person can be rendered proof against T. R. he is proof against the bacillus itself. Koch affirms that he has made such numerous experiments with T. R. that no doubt can exist as to the correctness of his statement.

The treatment is very simple. Injections are made, as with tuberculin, in the back with a syringe. The fluid contains in one cubic centimetre, eight milligrammes of solid, and by dilution with salt solution, the proper dose is obtained. One five-hundredth of a

¹ Deutsche medicinische Wochenschrift, April 1, 1897.

milligramme is given first. This is such a small dose that very rarely any reaction sets in. When there is reaction, the dose must be still further diluted. The injections are made about every second day, and the dose is increased so slowly that the temperature seldom rises above half a degree. As a rule, the dose is increased up to twenty milligrammes, and if no reaction is perceptible, the injections are suspended. Koch has gained the impression that complete immunity is attained about two or three weeks after the application of large doses. The cure of tuberculous guinea-pigs succeeds only if the treatment is begun early. This is the same with human patients.

Koch asserts that this preparation has been applied in a great number of suitable cases, especially of lupus, and in early phthisis, and that he has achieved without exception a success far greater than was ever obtained with ordinary tuberculin.

In Koch's article, as originally published in the Berlin journal, mention is made of the commercial house charged with preparing and selling the new products. In short, the new tuberculin has become a proprietary preparation, with exclusive rights conferred on a certain firm. Koch's article, in a true commercial spirit, was withheld from publication *five months* till this pharmaceutical house was ready to supply the market; then the new discovery was trumpeted through the secular press some time before the publication of the article and telegraphed abroad with the name of the firm favored with the sale of the new product. The Berlin medical press and some of the Paris medical journals have very properly denounced the whole transaction as unworthy of a man of Koch's scientific eminence.

There is, to be sure, something to be said on the other side in regard to the preparation of an article requiring such careful and precise manipulation. But this difficulty could doubtless have been met in a more truly professional spirit. Whether the matter of Koch's new announcement is better than the manner, and is going to respond more satisfactorily than the first tuberculin to the hopes of the scientific world and the prayers of humanity, time must and will be allowed to show.

THE ANATOMICAL NOMENCLATURE OF THE NERVOUS SYSTEM.

It is said that there are something over ten thousand names in the chief languages applied to the six hundred parts of the central nervous system, which would indicate that the nomenclature of that part of anatomy, like the rest, is in a state of considerable confusion. Against that confusion Dr. Wilder, of Ithaca, has battled for many a year, and in a recent number of the *Journal of Comparative Neurology*¹ he has summed up the result of his labors.

That the nomenclature advocated by Dr. Wilder possesses many advantages must be admitted. The

terms are often briefer, they can be inflected, they are of classical origin, and they are often more definite; but they are in an unknown tongue, and the constructions of the English language are set at naught. Desirable as such a nomenclature might be if applied to a new subject, it is to be remembered that reforms are of slow growth in this as in every other matter. Many good New Englanders reckon to this day in the shillings and pence of the colonial era, and the most ardent advocate of the metric system will be puzzled to tell how many kilometres he "scorched" on his new '97 wheel. *Præcibrium*, *paracœle*, *ripa* and *diacœle*, are strange terms even to the few who know something of cerebral anatomy, and the lover of English undefiled shudders at *dorsad* and *caudad*. Some love a good re-sounding term like *iter a tertio ad quartum ventriculum* in spite of the American desire for a short word, and others cling to the old associations with *Rolando*, *Willis* or *Herophilus*. Even the acceptance of a few of Dr. Wilder's terms by the American Neurological Association does not prevent its members from still talking of dorsal instead of thoracic vertebrae.

Dr. Wilder with reason criticises the report of the *Anatomische Gesellschaft* and his in that they have failed to consider the reforms he urges, but so sweeping a change in nomenclature is not to be expected. A few of his suggestions have been accepted and more undoubtedly will be adopted, but the knowledge of the anatomy of the brain possessed by the majority of physicians is unfortunately limited, and too sudden an overturn of their scanty knowledge might lead to despair and an abandonment of effort to know anything of so complicated a matter.

MEDICAL NOTES.

NURSES TO START FOR CRETE.—Mrs. Ormiston Chant, the social reformer, and six nurses, started from London, April 8th, for the Island of Crete.

APPOINTMENT.—Dr. Robert Abbé has been appointed to the newly created position of assistant surgeon to Roosevelt Hospital, with a seat in the Medical Board.

INFLUENZA IN LONDON.—Influenza in London is rapidly declining. For the past seven years it has been more or less fatally prevalent in that city during the month of March and early part of April.

A NEW HOSPITAL IN LONDON.—The Hebrews in London propose to celebrate the sixtieth year of the Queen's reign by erecting and endowing a home and hospital at Tottenham for Jewish incurables. A site of about four acres has been acquired, and accommodation will be provided for fifty patients.

INTERNATIONAL MEDICAL CONGRESS.—It is reported that Germany has notified the Russian government that it will withdraw its representation unless all restrictions with regard to the passports of the Hebrew members of the German delegation are at once with-

¹ December, 1896.

drawn. It is insisted that the Jewish members of the Congress shall receive from the Muscovite authorities identically the same treatment as their Christian colleagues.

A PROPOSED BRITISH NATIONAL MEMORIAL OF JENNER.—On March 31st, a meeting was held in the theatre of the University of London, with the object of establishing a national memorial of Edward Jenner. The Duke of Westminster presided, and expressed the opinion that the proper place for the memorial statue was Jenner's native village of Berkeley. Lord Herschell introduced the resolution, "That the present is an appropriate time to inaugurate a work of national utility in honor of Edward Jenner." Lord Lister proposed "That a subscription be set on foot with a view of promoting, in connection with the British Institute of Preventive Medicine, but in a manner distinguished by Jenner's name, researches on the lines which he initiated." Both were carried unanimously.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, April 21, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 74, scarlet fever 72, measles 179, typhoid fever 7. For the week ending April 28, the following cases were reported: diphtheria 109, scarlet fever 78, measles 203, typhoid fever 4.

FAILURE OF THE BILL TO REGULATE HOSPITALS FOR CONTAGIOUS DISEASES.—The Massachusetts House of Representatives has rejected, by a vote of 106 to 78, the bill to regulate Hospitals for Contagious Diseases. This question was discussed editorially in our issues of March 18th and 25th, when the original bill was before the committee.

SUFFOLK DISTRICT MEDICAL SOCIETY, CENSORS' EXAMINATION.—The Censors of Suffolk District Medical Society, officiating for the Society at large, will meet to examine candidates for admission to the Massachusetts Medical Society at 19 Boylston Place on Thursday, May 13, 1897, at 2 P. M. Candidates should make personal application to the secretary, John Dane, M.D., 29 Marlborough Street, Boston, and present their medical diploma, or its equivalent, on May 10th, 11th or 12th, between 2 and 3 P. M.

SUFFOLK DISTRICT MEDICAL SOCIETY.—At the annual meeting of this Society on April 24th, the following officers were elected for the ensuing year:

President, Francis H. Brown. Vice-President, Herbert L. Burrell. Secretary, John Dane. Treasurer, Augustus S. Knight. Librarian, B. Joy Jeffries.

Commissioner of Trials, C. W. Swan. Member of Nominating Committee of the Massachusetts Medical Society, W. L. Richardson. Committee of Supervision: S. L. Abbot, A. D. Sinclair. Committee on Social Meetings: Paul Thorndike, John Dane, J. T. Bowen, J. Bapst Blake. Censors: J. B. Ayer, E. O. Otis, George Haven, Harold Williams, John C. Munro.

Councillors: J. B. Ayer, E. M. Buckingham, J. F. Bush, A. T. Cabot, B. F. Campbell, D. W. Cheever, Hasket Derby, F. W. Draper, T. W. Fisher, R. H. Fitz, C. F. Folsom, W. W. Gannett, M. F. Gavin, George W. Gay, C. M. Green, W. H. H. Hastings, J. Homans, B. J. Jeffries, George F. Jelly, F. I. Knight, A. L.

Mason, J. H. McCollom, A. B. Morong, F. G. Morrill, A. H. Nichols, C. B. Porter, A. Post, J. J. Putnam, J. M. Putnam, W. L. Richardson, M. H. Richardson, T. M. Rotch, G. H. M. Rowe, F. C. Shattuck, G. B. Shattuck, A. M. Sumner, C. W. Swan, J. B. Swift, G. G. Tarbell, H. F. Vickery, J. C. Warren, J. C. White, E. N. Whittier.

SMALL-POX IN SOMERVILLE, MASS.—A case of small-pox has been discovered in Somerville. The house of the patient has been quarantined, and his family vaccinated. The Somerville Isolation Hospital was destroyed by fire a short time ago.

AN ENDORSEMENT OF THE COMMISSION ON PUBLIC CHARITABLE AND REFORMATORY INSTITUTIONS.—At the annual meeting of the Middlesex South District Medical Society, held at Watertown, Mass., April 21, 1897, the following resolutions were unanimously carried:

Resolved, That the Middlesex South District Medical Society fully endorses the recommendations of the "Commission to Investigate the Public Charitable and Reformatory Interests and Institutions of the Commonwealth."

Resolved, That the method of dealing with the Insane, advised by the Commission, commends itself to this Society as one which will give them humane, scientific and therefore, truly economical care.

PRIVILEGED COMMUNICATIONS AND PHYSICIANS.—At the trial of a recent will case in the Middlesex Superior Court in Cambridge, Mass., Dr. D. W. Cheever, surgeon in the Boston City Hospital, gave evidence as to having treated the testator from January of the year 1882 to September, 1884. He at first declined to state the nature of the disease, pleading professional confidence as a reason, and mentioning the fact that in eight other States there were laws prohibiting such communications. On the court deciding that he should answer, the witness gave his testimony without reserve. The court held that according to the laws of Massachusetts *lawyers* only were allowed privileged communications.

NEW YORK.

FIRE AT THE WOMAN'S MEDICAL COLLEGE.—The New York medical schools have been great sufferers from fire during the past season. First came the Polyclinic fire, then the one at Bellevue Hospital Medical College, and on April 22d the Woman's Medical College of the New York Infirmary, on Livingston Place, Stuyvesant Square, was partially destroyed. The loss on the building is estimated at \$20,000 and on the contents at \$35,000; but the damage is said to be fully covered by insurance.

THE BILL TO SUPPRESS THE ABUSE OF MEDICAL CHARITY.—It is learned that in the bill for the repression of the abuse of medical charity, as it finally passed the Legislature, the regulations governing all dispensaries offering free treatment are to be formulated by the State Board of Charities instead of by a board composed of representatives of various medical societies, as in the original bill drafted. There were also some other minor modifications in the act.

BEQUESTS TO NEW YORK HOSPITALS.—Andrew J. Garvey, a prominent member of the Tweed ring, who died recently in England, bequeathed half of

his fortune to various hospitals in New York. He is said to have made over a million dollars through frauds on the city, but he saved himself from prison by turning informer on his comrades, and he also managed to retain the spoils which he had accumulated.

DEATH OF DR. LEROY McLEAN.—Dr. Leroy McLean, one of the most prominent physicians of Troy, died at his residence in that city on April 23d, after a long illness. He was a native of Washington County, New York, and in the late war was a surgeon in the Union Army.

A DEATH FROM YELLOW FEVER IN NEW YORK.—Otis E. Bullock, a young man twenty-one years of age, of Haverhill, Mass., who arrived from Colon on board the Panama Railroad steamer *Finance* on April 22d, was found at Quarantine to be suffering from yellow fever, and was transferred to the hospital on Swinburne Island, where he died the same day. The diagnosis was fully confirmed by an autopsy, and the body was afterwards cremated. Dr. Doty, Health Officer of the Port, reports that a number of cases of yellow fever have recently occurred at Colon.

SMALL-POX IN NEW YORK CITY.—During the week ending April 24th there were three deaths reported from small-pox. Since the disease recently appeared twenty-one cases in all have been removed to the Hospital on North Brother's Island from the city and from the Asylum for Idiots on Randall's Island, where several of the children were attacked. The total number of deaths in the city was 749, against 783 during the week ending April 17th. In an estimated population of 1,977,850 this represents an annual death-rate again below 20 per thousand. The mortality from influenza decreased from 17 to 11, but the deaths from diphtheria increased from 20 to 39.

Miscellaneous.

OPENING OF A NEW RECEIVING WARD AND CLINICAL OPERATING HALL AT THE PENNSYLVANIA HOSPITAL, PHILADELPHIA.

WITHIN the last few years the venerable Pennsylvania Hospital has been thoroughly renovated and to a large extent remodelled, while its resources have been largely increased by the erection of additional buildings which are models of modern hospital construction.

The latest of these is the "Garrett Memorial," which was opened April 23d, and which is intended to be used as a reception ward, a clinical and operating hall and also a surgical ward for children. It also contains elaborate apparatus for disinfection of clothing and for the preparation of aseptic dressings for surgical purposes. The apparatus for the preparation of instruments and dressings for operations, as well as for the filtration and sterilization of water, is of the most approved form. One peculiar feature of the building is a special room for operations upon in-

fectious or septic cases, so constructed that the apartment can be filled with live steam and the walls, ceiling and floor thoroughly flushed with streams of hot water, after each operation. There are also rooms for the administration of anesthetics prior to operation, and others where patients may be kept until after their recovery from the anesthesia. There are special apartments for the surgeons when preparing for an operation, which include facilities for bathing. The nurses also have a room immediately adjoining the clinical amphitheatre where they can make themselves ready, in accordance with the requirements of modern surgery, to assist at operations. There are also rooms for examination of patients, including one containing a Röntgen x-ray outfit, and also microscopic and photographic apparatus.

The building is situated at the northeast corner of the grounds, at the southwest corner of 8th and Spruce Streets. It is three stories in height, and is built of pressed brick with brown-stone facings. It has two entrances—one from the street, through a colonial doorway, which is to be used by students attending the lectures; and one in the south for patients, opening on the enclosure. For the sick and injured the entrance is through the hospital gate, midway between Spruce and Pine Streets, on 8th Street, from whence a cemented drive and sidewalk lead to the new building 100 feet to the north. A large glass *porte-cochère* overhangs its entrance.

The dedication services, which were appointed for 3.30 p. m. were largely attended, and consisted in addresses delivered by members of the medical staff introduced by Mr. Benj. H. Shoemaker, President of the Board of Managers.

Dr. Thomas G. Morton, the senior surgeon and member of the medical staff, delivered the opening address, in which he first described the various features of the new building, which had been planned by Addison Hutton and Dr. Thomas S. K. Morton, and which is believed to be equal to any other structure of its description in the world—if, indeed, it is not superior to all others. It was erected through the generosity of one member of a family of philanthropists to whom the hospital was already indebted for very generous gifts. Dr. Morton explained the use of the sterilizing apparatus and incidentally referred to the antiseptic methods of wound treatment. He also spoke of the services to medical education in this country which have been rendered by the Pennsylvania Hospital, which soon after opening in 1752 began to utilize the material for clinical instruction by admitting students to the wards. The present clinical hall is an evolution of the idea which led to the construction of the first clinical lecture hall in the rotunda of the centre building early in the century. Subsequently, that was found to be too small and the more commodious octagonal lecture-hall was opened in 1868, which in turn is now abandoned for the present magnificent structure.

The development and growth of the hospital were attributable largely to its physicians. The early members of the medical staff were men not only of eminence in the profession but also occupied positions of trust and honor in the community. Thirteen of the twenty who served prior to the opening of the present century, were active in organizing the American Philosophical Society. Several were among the founders of the College of Physicians of Philadelphia,

and others became professors in the College of Philadelphia, which afterwards became the University of Pennsylvania. They were men of affairs, leaders of public opinion, who served their country not only in their profession but also in military and in civil life. Under the guidance of such men the hospital was enabled to take a leading place as an educational institution, and its influence has been widely felt in the development of the country.

Dr. J. M. DaCosta, whose Address will appear in full in next week's JOURNAL, also alluded to the services of members of the medical staff, confining his remarks mainly to those of more recent date. As to the value of their teachings he stated that many an enduring gift had been in this way given to the profession at large.

"Clinical teaching" he said, "rightly conducted is a benefit to the sick. There is an opinion that it is only of use to the medical profession and especially to those about to enter it. To them, indeed, it is invaluable, and through them to whole communities. But it is valuable, too, to the patients themselves. The very publicity of it, the hundreds of critical eyes with which it is observed, ensure that the best thought is given to the helpless and the sick. There is very rarely any objection on the part of the patient for having his case publicly investigated. On the contrary he likes it, he regards it as a mark of interest."

In conclusion, a strong plea was made for the establishment of a well-equipped laboratory for clinical, pathological and chemical investigations, which advances in medicine and surgery have now made indispensable in diagnosis and treatment.

Dr. John B. Chapin, Superintendent of the Department of the Insane, made the concluding address in which he traced the development of this department, and dwelt upon the humane methods which have always characterized the management of the insane in the Pennsylvania Hospital.

The company was then invited to inspect the hospital and partake of a lunch provided for them by the steward, Mr. Test, in the hall of the centre building. About three hundred invited guests were present, including many prominent members of the medical profession.

PARALYSIS OF THE POSTERIOR CRICO-ARYTENOIDS.

At a recent meeting of the Lyons Society of Medical Sciences, M. Benoud¹ reported a case of paralysis of the posterior crico-arytenoids during the course of a typhoid fever. The paralysis came on during the third week of the disease, and was accompanied with pain and inspiratory dyspnea with stridor; which increased rapidly, so that during a bath the patient became almost asphyxiated, and preparations were made to do tracheotomy. Microscopic examination showed that it was not a case of typhoid laryngitis, but that the vocal cords fell together during inspiration. A paralysis of the soft palate came on later, and served to confirm the diagnosis of the laryngeal lesion.

Paralyses in the course of typhoid fever are rare. In a recent monograph by Bouley and Mendel 17 cases are reported, of which six concerned the posterior crico-arytenoids.

¹ Lyon Médical, March 28, 1897.

Obituary.

WILLIAM G. WHEELER, M.D.

DR. WILLIAM G. WHEELER, of Chelsea, Mass., whose death was noted in the JOURNAL last week, was one of the most prominent, as well as one of the oldest practitioners of that city. He was born at Columbus, N. Y., August 3, 1821. His early education was obtained at Foster's private school, and at Benton Academy, Little Falls, N. Y. He practised medicine at Little Falls for two years and then moved to Chelsea. When Chelsea was a town he cared for the sick at the poor farm, and later served as city physician. He was a member of the Chelsea School Committee for a number of years. During the Civil War he was one of the examining physicians for the federal government.

He was a member of the American Medical Association; fellow of the Massachusetts Medical Society; member of the Boston Society for Medical Improvement; of the Boston Gynecological Society, being its president in 1875 and 1876; vice-president of the Suffolk District Medical Society in 1861; honorary member of the surgical staff of the Lynn Hospital since 1888, and consulting physician to the Massachusetts Soldiers' Home since 1890.

Dr. Wheeler was influential in securing from the late Hon. Rufus S. Frost the gift of the Frost Hospital, and after the founding of this institution was deeply interested in its welfare.

His interesting account of "An Incident in the Early History of the Introduction of Sulphuric Ether as an Anesthetic," read at the Massachusetts General Hospital on December 1, 1896, and published in the JOURNAL January 7, 1897, will be remembered by our readers.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, APRIL 17, 1897.

Cities.	Estimated population.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Newburyport . . .	14,554	5	0	—	—	—	—	—	
Amesbury . . .	10,920	—	—	—	—	—	—	—	

Deaths reported 3,389; under five years of age 1,091; principal infectious diseases (small-pox, measles, diphtheria and croup,

whooping-cough, erysipelas, diarrheal diseases and fever) 347, acute lung diseases 566, consumption 381, diphtheria and croup 135, diarrheal diseases 57, scarlet fever 40, typhoid fever 31, whooping-cough 30, measles 22, cerebro-spinal meningitis 21, erysipelas 11.

From typhoid fever Chicago 8, Philadelphia 5, Boston, Washington and Pittsburgh 3 each, Brooklyn, St. Louis and Providence 2 each, Baltimore, Cleveland and Springfield 1 each. From whooping-cough Philadelphia 12, New York and Chicago 6 each, Brooklyn 2, St. Louis, Washington, Pittsburgh and Woburn 1 each. From measles New York and Brooklyn 7 each, Chicago 5, Lynn, New Bedford and Springfield 1 each. From cerebro-spinal meningitis Boston 8, New York 5, Washington, Providence, Worcester, Somerville and Everett 1 each. From erysipelas Philadelphia 4, New York 3, Boston 2, Baltimore and Cleveland 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,992,524, for the week ending April 10th, the death-rate was 18.6. Deaths reported 3,917; acute diseases of the respiratory organs (London) 271, whooping-cough 106, measles 88, diarrhea 46, diphtheria 43, scarlet fever 31, fever 24.

The death-rates ranged from 11.2 in Brighton to 27.1 in Salford; Birmingham 19.2, Bolton 26.2, Bradford 17.6, Cardiff 16.6, Gateshead 17.0, Hull 18.3, Leeds 16.0, Leicester 19.0, Liverpool 23.1, London 17.5, Manchester 26.7, Newcastle-on-Tyne 20.0, Nottingham 19.7, Portsmouth 16.0, Sheffield 18.1.

METEOROLOGICAL RECORD

For the week ending April 17th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE TWO WEEKS ENDING APRIL 24, 1897.

J. W. BAKER, surgeon, detached from the "Bennington" on relief and placed on waiting orders.

M. H. SIMONS, surgeon, orders to the "Columbia" revoked and placed on waiting orders.

E. Z. DERR, surgeon, orders detaching him from the "Columbia" revoked.

E. S. BOGERT, passed assistant surgeon, detached from New York Navy Yard and ordered to the Marine Rendezvous, New York.

D. O. LEWIS, surgeon, ordered to Annapolis as member medical examining board, May 17th.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 17, 1897, TO APRIL 23, 1897.

Leave of absence for three months, with permission to apply for an extension of one month, to take effect upon his relief from duty at Fort Bliss, Tex., is granted CAPTAIN OGDEN RAPPERTY, assistant surgeon.

Leave of absence for one month, with permission to apply for an extension of one month, is granted MAJOR JOHN VAN R. HOFF, surgeon, Vancouver Barracks, Wash.

MAJOR CHARLES SMART, surgeon, is ordered to proceed to Fort Sill, O. T., at the proper time to accompany Troop E, 1st Cavalry, on a practice march, for the purpose of making a thorough test of the emergency ration recently established by the President, and when his services are no longer required with the command, to return to his station in this city, Washington, D. C.

CAPTAIN JAMES D. GLENNAN, assistant surgeon, is relieved from duty at Fort Sill, O. T., and ordered to Fort Clark, Tex., for duty, relieving MAJOR HENRY S. KILBOURNE, surgeon.

Leave of absence for one month is granted CAPTAIN WALTER D. McCAW, assistant surgeon, to take effect upon arrival at Fort Ringgold, Tex., of FIRST-LIEUT. CARL R. DARNALL, assistant surgeon.

Upon return of FIRST-LIEUT. FREDERICK P. REYNOLDS, assistant surgeon, to Fort McIntosh, FIRST-LIEUT. CARL R. DARNALL, assistant surgeon, will proceed to Fort Ringgold, Tex., and report for temporary duty during the absence on leave of CAPTAIN WALTER D. McCAW, assistant surgeon.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE FIFTEEN DAYS ENDING APRIL 15, 1897.

BANKS, C. E., surgeon. To inspect service at New Orleans, La., Mobile, Ala., Savannah, Ga., Charleston, S. C., and Wilmington, N. C. April 3, 1897.

MCINTOSH, W. P., passed assistant surgeon. Granted leave of absence for one day. April 5, 1897.

STONER, J. B., passed assistant surgeon. To proceed on or about April 12th, from Savannah, Ga., to Norfolk, Va., for duty. April 2, 1897.

GEDDINGS, H. D., passed assistant surgeon. Detailed to represent Department at Twelfth International Medical Congress, to be held in Moscow, Russia, August 19-26, 1897.

WERTENDAKER, C. P., passed assistant surgeon. Granted leave of absence for three days from April 17, 1897.

OAKLEY, J. H., passed assistant surgeon. When relieved at Philadelphia, Pa., on or about April 8, 1897, to proceed to Savannah, Ga., for duty. April 2, 1897.

PROCHAZKA, EMIL, assistant surgeon. When relieved at Delaware Breakwater Quarantine, on or about April 20, 1897, to rejoin station at Reedy Island Quarantine. April 6, 1897.

CUMMING, H. S., assistant surgeon. To proceed on April 8, 1897, from New York, N. Y., to Philadelphia, for duty. April 2, 1897.

PROMOTION.

Assistant Surgeon J. H. OAKLEY commissioned as passed assistant surgeon, April 7, 1897.

SOCIETY NOTICE.

THE SUFFOLK DISTRICT MEDICAL SOCIETY, SURGICAL SECTION. — Owing to the fact that the Medical Congress in Washington comes on Wednesday, May 5th, the last meeting of this Section for the year will be held at the Medical Library, 19 Boylston Place, on Friday evening, April 30th, at 8 o'clock, instead of on the above date.

At 8.05 P. M. "The Incision and Method of Procedure in the Removal of Diseased Processes in the Neck, occupying the Space behind the Sterno-mastoid Muscle," by Dr. Frank Hartley, of New York. The paper is a description of Dr. Hartley's operative method in such cases, and the subject is considered under the headings: "The Incision," "The Exposure of the Field," "The Resulting Scar." Dr. G. H. Mooks will open the discussion of this paper.

At 8.45 P. M. "Projection Demonstration of an Unusual Degeneration in the Spinal Cord due to Metastatic Carcinoma of the Spine," by Dr. J. H. Wright.

At 9 P. M. "Deformities of the Feet in Art," by Dr. E. H. Bradford. Illustrated by the stereopticon. Synopsis: A description of the shape of the foot as represented in Barbaric, Egyptian, Greek, Roman and Modern art; a description of the shape of a normal foot, and of the foot as distorted by footwear; a description of the Greek sandal and its effect upon the foot; evidence of sandal distortion seen in Greek and Roman art which is copied in modern art.

PAUL THORNDIKE, M.D., Secretary, 244 Marlborough St.

RECENT DEATH.

CARL EISENLOHR, M.D., of Hamburg, eminent neuropathologist and anatomist; author of "Spinal Lesions in Pernicious Anemia"; "Pathologic Anatomy of Central Paralysis of the Larynx"; "Simulation of Tabes by Specific Chronic Meningitic Affections of the Spinal Cord," etc., died recently at the Madeiras, of tuberculosis, in his fifty-first year.

BOOKS AND PAMPHLETS RECEIVED.

Addresses.**OPENING OF THE GARRETT MEMORIAL CLINICAL HALL AND RECEPTION WARD.¹**

BY J. M. DA COSTA, M.D., LL.D., PHILADELPHIA.

It is difficult for any one intimately connected with an institution so old and renowned as the Pennsylvania Hospital to estimate fully the influence on thought and action of its very antiquity and renown. From the rooms that preceded the one we inaugurate, from the old rotunda, from the newer building in which until now successive generations of eager students assembled, have gone forth lessons that stamped themselves into the professional mind: lessons that stood by the listener in many a trial; lessons of readiness, of expertness, of cool determination in the surgeon; of profound analysis, of keen detection, of skill in meeting untoward symptoms, in the physician.

In the rooms that were anterior to this, have stood and taught those who were not unworthy successors to Rush, who for thirty years was the most conspicuous medical figure in this hospital — as, indeed, by his learning, captivating eloquence, and ardent zeal, he was the most conspicuous figure in the profession in the United States; and to Physic, the dignified surgeon, who, bringing with him into our century the appearance and manner of another time, stood before his class, with his hair powdered and clubbed, their idol, as in the tones of his cultivated voice he gave admirable illustrations of the conservative surgery of which he was the great exponent.

In those rooms taught John K. Mitchell, the versatile and gifted, with the eye of genius foreseeing the part minute organisms play in the production of disease; George B. Wood, as methodical and accurate in his statements at the bedside as everywhere in his respected career; William Pepper, clear in his descriptions and consummate in unravelling obscure processes; William Gerhard, take him for all in all, the greatest observer and clinician America has produced; John F. Meigs, inheriting with his famous name an interest in this hospital from the illustrious and inimitable teacher, whom also it is our boast to have had on our list, and showing here the same skill and kindness that made him the most sought-after physician in the community. In the old rooms also has been heard the voice of Barton, the pride of his colleagues, whose wonderful skill and ingenuity remained a tradition for long years, joined to regret for the early retirement from a profession in which, still young, he attained the first rank; of Norris, the truthful, honest, conscientious gentleman and teacher; of Joseph Pancoast, the brilliant surgical artist, devising processes that seemed to be the result of intuition, and practising, long before it was taught, a kind of antiseptic surgery, of which he himself did not recognize the importance or wider application; and of Agnew, the most esteemed man of our day in the American profession, cool, skilful, daring, yet of the soundest judgment, and a clear, concise, admirable teacher.

Thus, from the days one hundred and thirty years ago, when Bond enthusiastically, with the full appro-

bation of the managers, introduced clinical teaching into the Pennsylvania Hospital, and therefore on this continent — for it was in this hospital that the first bedside instruction in medicine was given — up to our time, there has been a succession of men bestowing publicly their best thought and experience without reward, or thought of reward, on those who were to come after them. It is scarcely possible for one who has long been associated with this hospital, and watched its workings with the eye of affection, to abstain from mentioning the present and his colleagues.

But if I may not speak of the living, I know and feel the influence they exert; I am aware of the love they bear this ancient and renowned institution; I see and hear in many ways how worthily they strive to emulate and equal the best records of the past, and to let the teachings of the Pennsylvania Hospital be distinguished, as in the past, for truthful exposition, sound practice, for enlightened, not blind, conservatism, for earnest wish and endeavor to contribute to medical progress.

The traits of the many distinguished teachers that have been connected with the hospital, and the influence of the character of the hospital itself, have formed indeed a great school of both practical medicine and surgery developing on rational lines. The men have formed part of the hospital; the hospital has formed part of the men. Nor is it only by oral teaching that the Pennsylvania Hospital has been helping to mould and guide the generations that have come here for instruction. It has also done its part in addressing the wider audiences to be reached through writings. It has given many an enduring gift to the profession at large. From this hospital have emanated or been chiefly promulgated the simplest, most direct and most successful treatment of fractures recognized and commended the world over; the method of manipulation in the reduction of dislocations; the use of animal ligatures in surgery; the distinction of typhoid fever as a separate form of fever in America, and as pre-eminently the fever of this country; some of the earliest, and to this day the best, descriptions of remittent fever and its consequences; the connections of joint affections with spinal diseases; the now universally adopted treatment of sunstroke by ice, and other forms of treatment that have become standard. To this — and it is but a partial list — may be added the description of many new operative processes by such masters in the art as Barton, Pancoast, Agnew, Levis; essays and clinical lectures innumerable by observers like Gerhard, Stewardson, Pepper and Hutchinson. And all have the same stamp of directness, truthfulness, careful observation and practical value. It is greatly to be regretted that so much of this literature is scattered, and has not been collected in the way Guy's Hospital and other great hospitals bring together the work of their men. Some years ago the attempt was made, and two volumes were issued; but the undertaking had to be abandoned with reluctance on account of the expense, with all the greater reluctance because the volumes were most warmly received and landed.

But to return to the clinical teaching of the hospital. It has taken a profound hold on the medical mind of the county, more profound, perhaps, than we who live in large centres realize. If I may be pardoned for speaking of what has happened to me personally, and of what is, I know, equally the experi-

¹ An Address delivered at the Pennsylvania Hospital, Philadelphia, April 23, 1897.

ence of my colleagues, I have often, when summoned out of town into a remote region, met a physician who, as soon as the immediate cause of our conference had been attended to, would ask me about some case he had heard expounded ten, fifteen or twenty years before at the Pennsylvania Hospital; or quote, in support of his view of the malady before us, a case there seen, and describe it so vividly that it seemed as if it had been but yesterday met with. And once, in the wilds of Colorado, encountering a middle-aged man who introduced himself to me, he asked, almost as his first remark, "Did the patient brought before us at a clinic," the date of which he mentioned "recover?" "What were the subsequent symptoms?" "And did all turn out as supposed?" I am ashamed to say his memory of all the circumstances was better than mine, and I could only give him a general answer, which, I fear, lowered me greatly in his estimation.

This wide diffusion of knowledge, this living interest in the doings of a hospital, is one of the advantages of clinical teaching, and it is certain that the hospital that neglects it, neglects a great means of doing widespread good. Moreover, it shuts itself off from the world; it has no ardent friends everywhere with its name on their tongues; it becomes purely local in its character and aims. It never takes rank with the first institutions of its kind, and must be content with a second or third-rate reputation.

Establishments for the sick existed in the time of the Romans. Hospitals, as we understand the term, have been founded since the fourth century. They were spoken of in the Council of Nicaea in 325, as institutions well-known and deserving support and encouragement. The Hôtel Dieu, with its motto, "Medicus et Hospes," began to receive the sick and destitute about the year 600. The Grand Hospital of Milan, with its several thousand patients, occupies the same building it did in 1466. But who has heard or knows anything of these hospitals, unless from their walls has gone forth something that has taught and been made use of to others; something that, in the minds of regardful men, has become identified with the progress of investigation and of ideas; something that, thrown on the billows of thought, has been carried far onward in the ocean of knowledge?

Clinical teaching, rightly conducted, is a benefit to the sick. There is an opinion that it is only of use to the medical profession, and especially to those about to enter it. To them, indeed it is invaluable, and through them to whole communities. But it is valuable, too, to the patients themselves. The very publicity of it, the hundreds of critical eyes with which it is watched, ensures that the best thought is given to the helpless and the sick. There must be accuracy, there must be the most strenuous effort for relief, where there are many eager watchers; and the influence of all this is, that the habit thus acquired is transferred to ward work, which in its turn becomes more exact. There is very rarely any objection on the part of the patient to having his case publicly investigated. On the contrary, he likes it, and is apt to seek it; he regards it as a mark of interest. To most teachers it has happened to see offended women bursting into tears, because, owing to inability to do so in the time allotted, they had not been taken to the clinic room after being spoken to about it; they were provoked at the favoritism thought to have been shown. Then it must be always remembered that the

very ill, or any whom it might possibly injure, are not taken before the class. No one with a spark of humanity thinks of such a thing. Certainly in this hospital the claims of patients have never been subordinated to bedside teaching, and, judging by the past, and the record to which we hold, never will be. We recognize, indeed, that we bring to this new room much from the time gone by. We are sensible that the old memories, the old traditions, the old spirit, are moving with us into this admirably arranged edifice. We feel their power, and no member of this ancient hospital can be unmindful of the strength of their hold on his fullest exertions and truest sympathies.

But the splendid room in which we are assembled has other uses than merely those connected with teaching. It is but a part of this Garrett Memorial Building that it will be alike a lasting monument to the generous philanthropists that endowed it, and to the forethought, the sagacity, the advanced knowledge, of those that planned it. Here is seen in a completeness nowhere, I believe, as yet equalled, an operating pavilion in which to make modern surgical treatment with its marvellous antiseptic results even more than ordinarily successful. The most minute details are attended to; years of professional experience have contributed to their elaboration. It is the perfection of mechanical ingenuity, the apotheosis of cleanliness, and, with its numerous attractive appliances, its movable tables, its large brass instruments, its adjacent tiled and marble dressing-rooms, would be fascinating, if one could only prevent a thought of the grim purpose of all this beauty from entering the mind.

Then, in this building with its combinations of means, other most valuable arrangements are manifest. There is a room devoted exclusively to operations upon those with infectious diseases that can be filled with live steam at a slight pressure; a room for the employ of the x-rays; there is electro apparatus for resuscitation and treatment; there are rooms for etherization. Then, in the other parts of the building — for it is more than a mere structure for lecturing and operating purposes — are rooms with every facility for immediate treatment of those brought here too ill or too severely injured to be moved further; there are "quiet" or recovery wards for those whom noise might injure, or who have passed the worst stages; and receiving wards for the reception and distribution to the appropriate places of all patients who are not too ill to be at once assigned to the main medical or surgical hospital. Here, then, is a building of wide interest and beneficial purpose, planned to meet what years of thought and experience have shown to be the most desirable, and executed in a manner that makes it not only a credit to the Pennsylvania Hospital, but to the city, and the country.

This building, too, is only one of the improvements that the present Board of Managers has gradually effected. They have step by step transformed the hospital. An admirable School for Nurses, with a separate building erected by the generosity of the Misses Blanchard; a Surgical Hospital, due to the munificence of the family of their former President, Wistar Morris, whose memory it worthily celebrates; an endowed Out-door Department, with every facility, the gift of William E. Garrett, Jr., one of the same family that gives this Memorial Building; the reconstruction of the old building in a manner that makes it the equal of any modern hospital, — all this surely

shows careful thought, far-sighted action. The community which believes in them has, little by little, occasionally in large sums, supplied them with the means, and, as it is seen how they are used, the springs of benevolence are expanding into broad streams. But they never can be too broad; the need is still great. This hospital, once to a considerable extent supported by those who entered it, is now almost entirely a free hospital, open at all times to those of every nationality and every creed. It still spends more than its income in their support; but, owing to the feeling of affection and pride which the community has for it, and the trust in a management which one of my former colleagues in an address has described as an active, intelligent body which never wastes, never misappropriates, it meets all demands, and increases steadily. It instinctively attracts to it, both in its managers and warm friends, those who love their fellow-men, who have a genius for philanthropy, and calls forth the large bequests that, in virtue of the affection and trust it has inspired, have alone made possible the changes in this hospital, which are so splendidly transforming it. If it continue to grow on these broad lines, it will not be long before, in addition to its antiquity and renown, it will be cited as being one of the foremost developments of the hospital idea in its best form among the modern hospitals anywhere. How all this would have delighted the benevolent souls who founded it! How gladly would Bond be with us to-day, viewing the growth of what his humanity suggested; and if, at the first meeting of the managers in December, 1756, to inspect the new wards before the sick were admitted, they could have foreseen to what the hospital would attain, what would have been their gratification. Perhaps the then President of the Board, the great American, Benjamin Franklin, did; and we can see in the pleasure in his benign face, in the light in his large gray eyes, that there has come to him the vision of what, through the natural sciences so dear to him, through the intelligent care of successors as worthy and as true to their trust as the friends that there surround him, had grown to be structures as complete as his imagination could have pictured, and as full of such appliances as his genius would have delighted in, and have surely added to. If there could come to us from that vision into the unseen world an expression of the appreciation it occasioned, warm words of approbation would surely reach those whose crowned efforts we are to-day inspecting.

But in all the changes, you, the Directors of this great charity, are effecting, one appeal we still make to you for action in a matter we know you are contemplating, and the importance of which our daily work forces on us. Give us a laboratory commensurate with the dignity and reputation of this hospital. It will be one more claim to gratitude, not only of the profession, but of the ill and injured, and, in its far-reaching results, of science and of posterity. It is no longer possible, it is becoming scarcely conceivable, that physician or surgeon can recognize disease as completely, or treat it as well as it can be treated, without the aid of laboratory facilities. Good work he may still do; but it will not be his best, and very far from the best that can be done. The time has passed for mere bedside labor, and in justice to the sick and injured, in justice to those exposed to possible contagion, laboratory work must supplement or guide

professional effort. Crown, then, your work with what is a recognized need of the day! Crown it with what will have the beginnings in it to develop with the wants a portentous future: crown it with a laboratory that now and in times to come will gladden those who look for guidance to this famed institution.

But we well know that for the great plan of which the completed structure we are now in is but a part, neither means nor opportunity exists to accomplish everything at once. For all that has been done already there is true appreciation and gratitude. For the building which is formally opened to-day, let us here express it. It stands as a monument of generosity, of enlightenment, and of ideas carried to perfect conclusion. Noble was the thought that conceived it; noble the thought in one who bore the name of a family that was already among the great benefactors of this hospital to add to a large bequest all that was needed to make the ardently desired beneficent plans a reality. In this Garrett Memorial Building, with an equipment in which nothing that the most advanced science can suggest is absent, pain is to be abolished, the best possible results ensured to the injured and distressed. From here lessons will go forth that will penetrate into every hamlet. Men now, men in years to come, will, during many an arduous struggle of a long career, turn to it with a sense of gratitude to the generous donor, through whose aid many of their difficulties are smoothed, by giving them an opportunity of witnessing how difficulties could be best overcome. And, further, he who is brought to these emergency wards, stricken or so injured that he cannot be moved another step without the gravest risk, the most destitute, the most wealthy, will be treated with appliances and in a manner that not many years ago the most powerful of the earth could not have commanded, and will learn to give thanks reverently, that there were noble-minded souls that so splendidly and thoughtfully provided for his dire necessities.

THE INFLUENCE OF ANESTHESIA ON THE SURGERY OF THE NINETEENTH CENTURY.¹

BY J. COLLINS WARREN, M.D., LL.D.,
President of the American Surgical Association.

GENTLEMEN: In selecting a topic for the annual address before such a body as this, it seemed to me desirable that the opportunity should not be lost to refer to the great event—the fiftieth anniversary of which has so recently been celebrated—an event which is so indelibly associated with American Surgery, but one in the commemoration of which the whole world joined with us.

As one of the staff of surgeons whose predecessors played so prominent a part in the introduction of anesthesia, I feel it incumbent on me to recall to you to-day some of the great changes which it helped to bring about. Let me turn your attention first to the century which preceded anesthesia.

It is difficult to realize the crude state of surgical knowledge and technique, and the relation it still bore to medicine even so late as the eighteenth century. In the previous century it was quite beneath the dignity of a medical man of standing to do any surgical

¹ Address delivered at Washington, D.C., May 4, 1897, before the American Surgical Association.

work.² Capital operations were, however, performed; for we read that Abraham Cyprionus, of Amsterdam, towards the end of the seventeenth century had performed lithotomy 1,400 times, and had also done abdominal section and had championed radical operations for hernia. Amputations were still performed in a very crude way; and in spite of Paré's teachings of one hundred years before, the management of hemorrhage appears to have been of a most primitive character. They were confined to fingers and toes, the forearm and the leg, amputations above the elbow or knee being regarded as a very dangerous procedure. The introduction of the tourniquet by Petit in 1718 brought with it a greatly improved technique, and made possible the selection of a point of election for amputations and the more general use of the ligature and secured the permanent abandonment of the cautery and styptics.

The prejudice against surgery, however, still prevailed, and those who continued to advocate a union of surgery with medicine lost caste with their associates. The students in Freiburg threatened to mob M. von Wuthwehr who in 1774 pointed out the necessity for a union of surgery with medicine. Towards the middle of this century schools of surgery were established for the benefit of the armies, and more attention was paid to instruction in this department at the universities. It is recorded, however, that in Germany at this period it was still considered an important part of the duties of the military surgeons to shave both privates and officers. Finally the Academy of Surgery was founded in 1731. The degrading association of barbers and surgeons was abolished in 1743 at Paris by an edict, and the example was speedily followed in 1745 by a similar act in the English Parliament. Freed from this galling servitude surgery became a separate and distinct branch to be ever afterwards studied and cultivated by educated members of the profession.³ In England particularly, owing to a more careful attention to the study of anatomy, the technique of surgical operations was greatly improved; and many of the methods of operating still in use to-day trace their origin to this period, such as operations for stone, the removal of tumors, and amputations. Pott undertook to divest surgery of much of its horrors.

A prophetic utterance of Pott's in one of his books is interesting: "Many and great are the improvements which the Chirurgie art has received within the last fifty years; and much thanks are due to those who have contributed them; but when we reflect how much remains to be done, it should excite our industry rather than our vanity. Our fathers thought themselves a great deal nearer to perfection than we have found them to be; and I am much mistaken if our successors do not in more instances than one wonder both at our inattention and ignorance."

The means of teaching surgery in Paris were limited, owing to the bad condition of the hospitals. In the Hôtel Dieu the operating theatre was in the St. Jerome Ward, where more operations are said to be performed than in any hospital in Europe. It was placed almost directly over the dead-house, the odors of which were quite perceptible. This ward accommodated twenty beds and an out-patient department.

In some of the adjacent wards the walls were soiled with expectorations and the floors with the discharges of the patients. The mortality in this hospital before the Revolution was one death to every four to five patients who entered. This included many persons who were hardly ill, the insane, and pregnant women. It was the rule that every case of amputation of a limb died.

In 1787 a school of practical surgery was founded by Desault, and the union of the teaching bodies in medicine and surgery was effected in 1794 when the *Écoles de Santé* were established. (These names were soon changed to the *Écoles de Médecine*.)

In England at this period surgery was in a much better condition. This was owing to the fact that the teaching was done largely in private schools and by men of world-wide reputation, for these were the days of the Bells and Hunter. Much as the latter did for anatomy, pathology and surgery, the prejudices of early education still clung to him. In 1753 Hunter was advised to study medicine rather than surgery, as a higher branch of the healing art; and he continued to regard an operation as a tacit acknowledgment of the insufficiency of medicine.

The horrors of surgery without anesthetics caused even surgeons themselves to look upon operative surgery as the lowest, poorest side of their profession. An operation was attended with almost the formality of an execution. The hardest of them are described as steeling themselves to the duty of operating. John Hunter spoke of operations as "humiliating examples of the imperfectness of the science," and pictures the operating surgeon "as an armed savage." He says: "No surgeon should approach the victim of his operation without a sacred dread and reluctance and should be superior to that popular *éclat* generally attending painful operations, often only because they are so."

Abernethy and Cheselden regarded operations as the reproach of surgery. Abernethy felt the strain of operating keenly, it was an added hardship for him to work on a patient who bore pain with fortitude. It is reported that he felt such repulsion to operations that he regarded them as having no place in surgery as a science.

An anecdote illustrating his feeling is related by his biographer. He was performing a severe operation on a woman. He had, as was usual, given her some words of encouragement before he began, and the patient was bearing the pain with great bravery. After suffering some seconds she said earnestly, "I hope, sir, it will not be long."—"No, indeed," replied Abernethy with great feeling, "that would be too horrible."

Cheselden is said to have seldom slept the night before an operation, so much did he dread it. Yet he was always cool and firm and dextrous in its performance.

It is probable that the dread of patients was not confined to the operation, for in early days the after-treatment was of the most torturing description. Every flap of skin instead of being reunited was cut away; every open wound was dressed as a sore, and every deep one was plugged up with a tent lest it should heal. No attempt at first intention was made. Long tents were thrust into wounds of the neck and cheek until the neck and head swelled enormously. Even in compound fractures dressings were thrust

² "Der medicus soll nicht schneiden, brennen, noch Pflaster auflegen, weil es wieder die Würde eines medici nationalis ist, denn es sind fast überall Barbierer, Bader und Steinschneider zu haben."

—Fr. Hoffmann, *Politischer Medicus*, S. 57.

³ History of Medicine, Dunglison.

between the ends of broken bones, as if they had been afraid of the formation of callus.⁴

At the opening of the century the improvement in the technique of the French school was very noticeable. This was due not only to the organizing powers of Napoleon, but to the development of military surgery. The influence of such work as was done by Larrey upon French surgery must have been enormous. It is said that Larrey performed alone in one day 200 amputations after the battle of Moskowa. His operations were not confined to amputations alone. His memoirs contain accounts of double amputations of the thigh, resection of the head of the humerus, pharyngotomy for the removal of a portion of a bayonet compressing the laryngeal nerve, and several cases of wounds of the abdomen complicated with injury of the intestines and bladder — all successful.

Larrey points out that Faure reported after the battle of Fontenoy that of 300 amputations only 30 recovered, but that in his cases three-fourths of the patients recovered. He attributed these results to primary operations and to a more simple, speedy and less painful method of operation. The asepis which in a certain number of cases must have existed is no doubt to be attributed to the rapidity, and therefore extreme simplicity of the method employed. Warm camphorated or sweetened wine often formed an application on the dressing, and may have contributed to the favorable result.⁵

As severe a test as any upon his method was the successful excision of loose cartilages from the knee-joint. The operation consisted of a single cut while the skin was held tense, and was practically a subcutaneous operation; a plaster was quickly clapped on, and the wound healed by first intention. We may still be able to learn something from these old campaigners!

Ollier says: "Rapidity was the quality demanded of all operators, with coolness and accurate anatomical knowledge. To operate well was a most difficult task. These operations were spectacular, but the dressers became afterwards but too well aware of their imperfections. This was particularly true of operations for disease as contrasted with those for traumatism. From 1836 to 1841 major amputations for disease gave a mortality of 50 per cent., while those for traumatism were only 3 per cent. The old operators endeavored to operate quickly; those of to-day endeavor to operate well."

The methods of civil practice were of the same rough and ready nature, and considerable skill was shown even by the country practitioner.

Blenkinsop⁶ describes his first experience of this kind — his cross-country riding with his principal to an amputation:

"In this kind of practice," said my companion, "it is necessary to have our instruments well secured: you see I have mine strapped fast around my body, I lost them once when I was going to amputate an arm; but I sharpened a cheese knife and borrowed the carpenter's saw, and got through it pretty well."

Then follows the graphic description of their arrival at a small farmhouse, of the doctor's interview with the man's wife, and of the nature of the injury, which involved an amputation high up in the thigh. The good wife having

been disposed of by being sent on a fool's errand, the case was explained to the patient. "Meanwhile every preparation had been made, and the man's consent had scarcely passed his lips when the tourniquet was applied and the first cut made. 'Attend to me,' said the doctor, 'watch everything I do and I'll explain it afterwards.' I felt a sad sickening and swimming of the head, but kept it down as well as I could, never for a moment taking my eyes off the quivering flesh. I nearly gave way when the bone was being sawed, but happily did not faint, and was as alert and attentive as possible. The operation, I think, scarcely exceeded ten minutes; and when the wife returned, the patient expressed himself comfortable and nearly free from pain."

It is hardly necessary for me to enumerate before such a body as this the rapid improvements which took place in surgery under the lead of the masters of the French and English schools in the early part of this century. The scope of operative surgery was thereby greatly increased, but some improved and elaborate methods brought with them prolongation of the operation and great increase of pain. People were afraid to undergo them. It was only the few who were made of sterner metal that had the hardihood to subject themselves to the ordeal. Such were the veterans of the Napoleonic campaigns, and Ollier relates how in his early days he had occasion to operate upon some of these men who refused etherization, which they regarded as the refuge of cowards, and laid motionless under the bistoury.

Of such material also was Dr. Ebenezer Hunt, who in 1789 consulted the councillors of the Massachusetts Medical Society in regard to a cancer near the ear. They decided that it must be eradicated. It was agreed that on the next day the operation should be performed. Accordingly, in a full meeting Dr. John Warren was selected as the operator. "We must bind his hands," said Dr. Warren. "No cable in Boston could hold them fast," rejoined Dr. Hunt. And with an effort that astonished the physicians themselves, he quietly laid his head upon the pillow and bade them begin. The ear was nearly cut off, though afterwards successfully replaced; then for thirteen minutes the operation continued, and every stroke of the knife so near the auditory nerve was like the report of a pistol. Dr. Hunt did not flinch in the least, though the sweat poured down his cheeks profusely. At length all was done; and as he raised his stately form, his first words were, "Now give me a certificate." Dr. Warren did not understand him, and asked for what reason. "Why," continued Dr. Hunt, "that I was not cropped for making money."

Cases have been reported of death from fright before the operation. Dupuytren said, "La douleur tue comme l'hémorrhagie."

John C. Warren, writing a year after the introduction of anesthesia, says: "In order to form a proper estimate of the value of the new practice, we should endeavor to realize the mental condition which precedes a surgical operation. As soon as a patient is condemned to the knife, what terrors does his imagination inflict! How many sleepless nights and horrible dreams and sinking of the heart does he experience? What apprehension of dangerous bleedings of wounds of vital parts and even sudden death does he paint to himself? And when to these is added the dread of insupportable pain, what a frightful picture presents itself to his mind! No wonder many persons are unable to bring themselves to submit. No wonder that some, worn out to desperation, are led to anticipate their sufferings by a voluntary death. Horror of the knife led a gentleman in this city afflicted with stone

⁴ Physic and Physicians.

⁵ Larrey relates that after the battle of Moskowa he performed amputations at the shoulder-joint on a *chef de bataillon*, who immediately after the wound was dressed, mounted his horse and departed for France. The horse died *en route*, but the officer arrived home safely.

⁶ Memoirs of Dr. Blenkinsop written by himself, London, 1852.

in the bladder to commit suicide." And well might he dread "the exquisite suffering, the spasmodic contraction of the wounded muscle, the irregular pouch-like contractions of the muscular coat of the bladder" which acted as obstacles to the operation of lithotomy before the days of ether.

The same author stated, in a paper in 1844, that in the course of forty years he had been called on to perform all the operations for stone which had been done in Boston. The whole number had not exceeded 25 cases.

It is not to be wondered that surgery languished, and that the old feeling against surgery which was so strong in the last century should leave traces of it among the representatives of surgery of the first half of the present century. Robert Liston, only two years before ether was first used, held practically the same opinion as to the operative part of surgery. In a lecture on operative surgery given in the University College Hospital in 1844, he says, "This is regarded as an inferior part of our professional duties, and truly it is so. The field of operative surgery, though happily narrowed, is still extensive." What a contrast! A great surgeon, two years before the dawn of anesthesia, rejoicing that the field of operative surgery was narrowed!

Students of surgery were taught how to give the least pain. Liston's directions were as follows:

"The divisions of the skin must inflict pain, but there is a way to render it less severe than it would otherwise be. The mode of cutting must be acquired to attain this desirable end. In the first place you must not divide the skin by scratches. You must carry the knife completely through the tissues at once, and doing it with rapidity you will save the patient a great deal of pain. Then again, by cutting the skin from within outwards, instead of from without inwards, you diminish suffering. This mode may be adopted in many operations. In hernias, the removal of tumors and in many amputations the parts may be divided in this way with one-twentieth part of the suffering often enough most unnecessarily inflicted."

Many surgeons abandoned the use of the knife and employed caustics in the eradication of tumors and other forms of chronic disease. Amputation by transfixion was generally adopted as being not only more rapid but much less painful.

II.

ANESTHESIA.⁷

The records of ancient history show that physicians and surgeons had in mind the possibility of an agent being discovered, the use of which might prevent pain in surgical operations. The various potions that were from time to time recommended for this purpose have little more than an antiquarian interest.

Although it has been said that the discovery of surgical anesthesia was a surprise, that its advent was marked by no tentative steps, that it appeared to have had no preliminary experimental stage, but burst like a revelation upon the medical profession as well as the community, virtually in the fulness of perfection,⁸ yet a retrospective glance at the history of the previous half-century will show that the idea was working in men's minds more powerfully than before, and that, as Paget says, a great truth lay unobserved, though it

was covered by only so thin a veil that a careful physiological research must have discovered it. Dotted here and there over the stretch of time we find suggestions and hints full of significance to-day, but which at that period found no congenial soil in which to germinate into a substantial addition to the knowledge of the world. One of the earliest of these was that of Davy.

After two years' work he published (when twenty-two) an essay on chemical and philosophical researches concerning nitrous oxide. He observed the peculiar phenomena which gave it the name of "laughing gas," and he saw people made temporarily insensible by it. Among other suggestions, being of a surgical turn of mind, he wrote in his papers: "As nitrous oxide in its extensive operation appears capable of destroying physical pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place."

It was during a popular exhibition given in Hartford in December, 1844, by Colton, that an individual while under the influence of the gas sustained several bruises which did not appear to cause him pain. This led one of the audience, Horace Wells, to remark, "A person might have a tooth extracted while under the influence of this gas and not experience pain." At Wells's request Colton went to his office and administered the gas to Wells while Riggs extracted a diseased tooth. The operation was a success, and Wells exclaimed after the effects of the gas had subsided, "A new era in tooth-pulling."

Ether came to be used on similar occasions as well as for "ether frolics" by medical students and others.⁹ An article written in 1818, probably by Faraday, states that, "When the vapor of ether mixed with common air is inhaled, it produces effects similar to those occasioned by nitrous oxide."

Ether had already been known at this time for nearly a century, the earliest period at which this fluid was distinctly mentioned by the name of ether being in the *Transactions of the Royal Society* for 1730, by Godfrey. From this time on the attention of chemists was much directed to ether. It was also often used in the last century for the relief of spasmodic asthma, phthisis and some other diseases of the chest. John C. Warren used it in Boston in 1805, to relieve the distress attending the last stage of pulmonary consumption, and very frequently after that, and notably in the year 1812 in the case of a member of his own family. Dr. Warren states that the manner in which it was applied was by moistening a handkerchief and placing it near the face of the patient.

In 1842 Dr. Crawford W. Long, of Georgia, removed a small encysted tumor about half an inch

⁷ The following letter is interesting in this connection:

CAMBRIDGE, February 15, 1897.

MY DEAR DR. WARREN:—Your note with regard to experiments with ether at the Massachusetts General Hospital in 1836 has reached me.

I remember well our amusements with sulphuric ether; Dr. Samuel Parkman was the house surgeon; I was the house physician, and Mr. C. K. Whipple, house apothecary.

We were especially jubilant when Mr. Whipple ordered a fresh quantity of ether, for it was apt to deteriorate by keeping. Each tested it by breathing it from the bottle till it produced unconsciousness, the others watching the different effects upon each.

We also experimented upon rats in a glass globe until they were entirely motionless, and often wondered that the treatment did them no harm. But with all our experiments we never thought of trying the sensibility under ether, even by pricking with a pin.

It was a great oversight.

As ever, sincerely yours,
MORRILL WYMAN.

⁷ As the *Journal* has recently published a number of papers upon the discovery and practical application of anesthesia, an abstract of this section of Dr. Warren's excellent address is given.

⁸ Hodges: *The Introduction of Surgical Anesthesia*.

in diameter, and he subsequently performed one or two other minor operations. He was not, however, fully satisfied that the anesthesia was produced by the ether, and that it was not the effect of the imagination. His patients were not carried beyond the "state of exhilaration," and he admits that having found ether impracticable, owing to the short duration of the anesthetic state, he therefore abandoned it. Long came very near achieving success, but the conditions surrounding him were unfavorable to such a result.

Meanwhile Wells followed up his personal experience by extracting several teeth, four in all, from several individuals. Wells visited Boston in January, 1845, and applied to Dr. John C. Warren for permission to try the gas. The experiment was made before the class but the patient screamed with pain, an insufficient amount of gas having been used, and the spectators laughed and hissed. It was not, therefore, until fifteen years after the death of Wells that Colton succeeded in bringing the gas into general use as an anesthetic agent in dentistry.

Anesthesia had been the dream of many a surgeon and scientist, but it had been classed with aerial navigation and other improbable inventions.

Warren refers to the sinking of the heart he felt in the distress of very painful operations to which no habit could render him insensible. Such feelings led to various trials with many different agents, with opium in all its forms and other narcotics, even in such quantities as really alarmed him without any satisfactory result.¹⁰ The first scientific account of the employment of hypnotic anesthesia for surgical purposes was given by Recamier and Baron de Potel in about 1821. It was recommended by Cloquet in 1829, who removed a cancer of the breast by its use without pain. Esdaile began to employ it as an anesthetic in surgery in 1846.¹¹ In Boston it was used successfully in the extraction of a tooth in 1836, the patient remaining under its influence about seventeen minutes,¹² but Warren states that mesmerism had never succeeded in cases under his inspection.

In 1839 Velpeau wrote: "To escape pain in surgical operations is a chimera which we are not permitted to look for in our day. A cutting instrument and pain in operative medicine are two words which never present themselves, the one without the other, in the minds of patients, and it is necessary for us surgeons to admit their association."

Scientific men were, however, now beginning to turn their attention to these anesthetic agents. For instance, M. Ducros¹³ presented a memoir to the Academy of Science in Paris in which he showed that sulphuric ether applied to the buccal and pharyngeal membranes of certain animals produced an immediate sleep and that it produced similar effects on man. He recommends its use in this way in hypochondriasis and insomnia. Rubbed upon the tongue, the soft palate and the tonsils ether produces an agreeable sleep. He advises its use also in puerperal eclampsia, in hysterical and epileptiform attacks and in trismus. Virchow also states that in Berlin in 1846 he had made independent investigations on "Aether Narkose."¹⁴

Warren said of ether in 1848: "Its general properties have been known more than a century, and the effect of its inhalation in producing exhilaration and insensibility has been understood for many years, not only by the scientific, but by the young men in colleges and schools, and in the shop of the apothecary who has frequently employed it for these purposes." Ether was even used in surgery, Thatcher, of Plymouth, employing it as a refrigerator for the reduction of strangulated hernia. Such was the situation when we first begin to hear of Morton.

[Dr. Morton's experiments and struggles with ether; his relations to his advisers; the final decision that the crucial test lay in a public demonstration in the operating theatre of a hospital in a surgical case; his introduction by Dr. J. Mason Warren to Dr. John C. Warren; the latter's consent to try the new agent; the story of the first operations have been already retold in the JOURNAL.]

Thus the great step was taken, the "thin" veil was suddenly thrown aside, and what had been before a surmise of the scientist, a pastime of the idle student, and the dream of the surgeon, suddenly assumed practical form and shape and became a living truth, revealed in all the fulness of perfection.

In looking back over the period just outlined, a half century later, it seems as if the observer could see with a clearer vision and reason with calmer judgment. The minor controversies of those days have already faded into the past, while the salient truths stand out all the more clearly.

In due course of time science gave first one and then another anesthetic to the world, but the world toyed with them for half a century, nearing and receding from the truth in a tantalizing way, until a practical man came forward, pushed aside one or two apparently unimportant obstacles, and, guided by good advisers, was fortunate enough to put the new method to that crucial test for which it had so long waited. As Ashhurst has well said: "Surgeons went on in every country cutting and burning, and patients went on writhing and screaming, until on the 16th day of October, 1846, when surgical anesthesia became the priceless heritage of the civilized world."

III.

SURGERY AFTER ANESTHESIA.

Warren, writing in 1848, says: "A new area has opened to the operating surgeon. With what fresh vigor does the living surgeon, who is ready to resign the scalpel, grasp it and wish again to go through his career under the new auspices! . . . Since the fear of pain has diminished, the number of surgical operations has remarkably increased, at least in our vicinity."

An editorial article in the *Lancet*, written about six months after ether was first used in Boston, states that the number of operations in the London hospitals had more than doubled.

Mason Warren writes: "The domain of surgery has been enlarged by admitting into the list of justifiable operations some whose severity would otherwise in most cases have prevented even the thought of attempting them."

Erickson writes, in 1878: "During the last thirty years the actual number of operations performed in hospitals has enormously increased, and probably in a

great measure owing to the employment of anesthetics."

Marshall, the emeritus professor of surgery at the University College Hospital in 1885, compared the surgical work of the hospital in Liston's time in 1844 and his own.¹⁵

Although the proportion of fractures and wounds was about the same in the two periods under comparison, the number of surgical cases admitted to the hospital in 1885 was more than double the number admitted in 1844. A numerical comparison, however, gives an inadequate idea of the increased amount of surgical cases; for in 1844 simple cases were treated as out-patients, and venereal cases in large numbers were admitted to the wards. In 1883 more patients with malignant growths came for operation. This was attributed, not to the increase of malignant diseases, but to the willingness of persons to be operated upon under anesthesia.

Diseases of the bones and joints did not differ much comparatively. Stricture of the urethra was operated upon very much more often in 1883.

In the whole year of 1844 there came into the surgical ward of the University College Hospital only one case each of ovarian tumor, of aneurism and vesico-vaginal fistula. Joux records¹⁶ that from 1830 to 1850 he found no recorded case of excision of the knee; but in 1850 to 1854 there were 21 cases. With the increase in surgical work came a great increase in the relative cost of hospital maintenance. In the University College Hospital the expenses for surgical supplies in 1844 was £206, and in 1883 £1,765, of which £1,275 went for modern surgical dressings. The cost of instruments in 1883 was more than doubled.

The following table, taken from the record-books of the Massachusetts General Hospital, enables one to compare the work done after the advent of anesthesia with the period immediately preceding it.

Operations.	For Five Years Before Anesthesia.		For Five Years After Anesthesia.	
	Number.	Mortality, Per cent.	Number.	Mortality, Per cent.
Total operations	184	6½	487	9
Tumors (excluding breasts)	39	5	122	3
Amputation of breast	13	8	30	10
Plastic operations	6	..	33	3
Amputations (hand, foot, arm, leg)	13	15	65	23
Hernia. Strangulated-gut freed by incision	5	60	1	..
Hernia. Reduced by taxis under ether	2	..
Hernia. Radical cure, plastic
Hernia. Radical cure, injection iodine	11	..
Colotomy	4	75

had no preliminary experience. The revelation upon the medical profession as well as the community, virtually in the fulness of perfection,⁸ yet a retrospective glance at the history of the previous half-century will show that the idea was working in men's minds more powerfully than before, and that, as Paget says, a great truth lay unobserved, though it

⁷ As the Journal has recently published a number of papers upon the discovery and practical application of anesthesia, an abstract of this section of Dr. Warren's excellent address is given.

⁸ Hodges: The Introduction of Surgical Anesthesia.

duction of ether was over two and one-half times as great as that in the five preceding years.

The question whether anesthetics increased mortality or not was one which was much discussed formerly. Simpson believed that they did not. Arnott brought forward figures to show that the mortality had been increased 12 per cent. in amputation and 28 per cent. in lithotomy. Erichsen also believed the mortality-rate had increased since the use of anesthetics in operative surgery. Curling gives the mortality of amputations of thigh and leg in the London hospitals for 1837 to 1843 at 41 per cent. During 1847, in 73 cases in which an anesthetic was given, the mortality was 19 per cent. At the Pennsylvania Hospital the mortality of amputation from 1835 to 1840 was 36 per cent.; from 1840 to 1845 it was 20 per cent. From 1850 to 1855 it was 23 per cent.; and from 1855 to 1860 it was 31 per cent. At the Massachusetts General Hospital the death-rate was, as a rule, increased in the different classes of operations. The rapidity with which certain operations were performed undoubtedly favored asepsis particularly in all aseptic cases, and probably in any operation which could be done quickly and thoroughly.

In many cases of spreading sepsis rapidity was a bar to thoroughness, and results were correspondingly unsatisfactory.

A young man presented himself at the Hôtel Dieu in 1845, with palmar abscess; but as no opening was made, the arm became involved the following day, pus having found its way under the annular ligament. The bistoury was produced, plunged deeply between the pronators and supinators of the forearm, and carried up rapidly from the wrist to the bend of the elbow: the arm fell open and a pint of matter instantly escaped, but with it jets of florid blood from the brachial end of the wound. The brachial artery had to be tied; and when the reporter left Paris, the surgeons were contemplating amputation at the shoulder joint.¹⁷

The contrast of anesthesia in such cases is a strong one. The days of anxiety which visited patients and their medical advisers previous to an operation were, with the discovery of anesthesia immediately swept away, and the problem of the relief of disease by surgery became vastly simplified. Surgeons could now operate promptly but with deliberation and thoroughness.

The enormous increase in the number of surgical cases brought about conditions for which hospitals and surgeons were alike unprepared.

When we reflect how few of the aids to surgical diagnosis were possessed by surgeons in 1846, the amount of work which they accomplished presents all the stronger contrast. They had no endoscope, no ophthalmoscope, no modern aspirating-needle, no clinical thermometer, and no laryngoscope. The stethoscopes were far from perfect. Examination of the blood and the quantitative analysis of the excretions were unknown. The microscope was just coming

I remember well our amusements with sulphuric ether; Dr. Samuel Parkman was the house surgeon; I was the house physician, and Mr. C. K. Whipple, house apothecary.

We were especially jubilant when Mr. Whipple ordered a fresh quantity of ether, for it was apt to deteriorate by keeping. Each tested it by breathing it from the bottle till it produced unconsciousness, the others watching the different effects upon each.

We also experimented upon rats in a glass globe until they were entirely motionless, and often wondered that the treatment did them no harm. But with all our experiments we never thought of trying the sensibility under ether, even by pricking with a pin. It was a great oversight.

As ever, sincerely yours,
MORRILL WYMAN.

But with this great increase in hospital activity came a corresponding increase in hospital pests; and it seems highly probable that during the twenty years following the introduction of anesthesia the opportunity to study septic diseases was greater than it ever had been. Mason Warren, writing in 1864, says: "I remember the time when, after an amputation or the excision of a breast or a large tumor, it was the universal rule to bring the edges of the cut integuments together nicely with straps, compress and a bandage with the full assurance of finding the wound nearly healed at the removal of the dressing. At the present day, however, such a result is seldom attained in city practice, union by first intention being for the past twenty years the rare exception, suppuration almost always ensuing in the deeper parts."

In about 1860 septic processes ran rife at the Massachusetts General Hospital, and the writer well remembers a virulent epidemic of hospital gangrene which got quite beyond the control of the surgeon. In the winter of 1867-68, in Vienna, Billroth's wounds were full of pyemia, erysipelas, and hospital gangrene, as the autopsy table but too frequently showed. Students and many practitioners of to-day have but a faint conception of the appearances of wounds and ravages of sepsis with which the surgeon of that time had to contend. As a house-officer at the Massachusetts General Hospital, I can well remember the tone of despair with which my father remarked, on learning from me of a fatal result following one of his operations, "I am often nearly disgusted with surgery!"

It would be beyond the scope of this article to undertake to show how the speculation of Liebig¹⁰ and others became tremendous truths in the hands of Pasteur and Lister, and the beneficent influences which the next great discovery of the century exerted upon human suffering.

It is interesting to note, however, the strangely appropriate order in which the great facts of medicine and surgery were given to the world in this progressive century. Hunter had already roused the thirst for knowledge which led others to rush forward and immortalize themselves as pioneers in anatomy, like Bichat, or modern surgery, like Cooper. Then came the work of the pathologists, such as Cruveilhier and the host of German pioneers. Just as the surgeon had brought his operative technique to a high degree of perfection, and science had made a practical instrument of the microscope, and preparation had been made for another advance all along the line, then came anesthesia, which widened the field of research sufficiently to occupy the world busily for another quarter of a century. It gave to surgery a more powerful impetus than it did to experimental medicine. At a moment when surgery seemed rushing wildly onward to its own destruction, with science lagging far behind, Lister came to the rescue, and scientific equilibrium was again restored.

Gentle as the Old Man produces an agreeable sleep. He advises its use also in puerperal eclampsia, in hysterical and epileptiform attacks and in trismus. Virchow also states that in Berlin in 1846 he had made independent investigations on "Aether Narkose."¹⁴

erating-theatres which surround it, but it will never be torn down. It will always remain as one of the conspicuous landmarks of this wonderful century — as a shrine of surgery sacred to that moment "when the fiercest extremity of suffering was steeped in the waters of forgetfulness and the deepest furrow in the knotted brow of agony was smoothed away forever."

AN HISTORICAL SKETCH OF ABDOMINAL SURGERY.¹

BY JAMES R. CHADWICK, M.D.,
President of the American Gynecological Society.

Two events have occurred during the past year of vital significance in the development of abdominal surgery. The death, on January 31, 1897, of the most active promoter of this branch of surgery — I allude, of course, to Sir Spencer Wells; and the semi-centennial celebration of the discovery of surgical anesthesia on October 26, 1896, without which discovery abdominal surgery could never have been extensively practised.

I propose to sketch briefly the steps by which abdominal surgery has been so marvellously extended during the lifetime of one man, laying special stress upon what might otherwise be inadequately remembered, his influence on the progress of this branch of surgery.

Abdominal surgery in general is all the outcome of ovariectomy, so that in its early days the history of the former is included in the history of the latter. For this reason we Americans have an additional incentive in reiterating the indisputable fact that the first operation was done on our soil by one of our own countrymen.

On the 13th day of December, 1809, in a frontier town of Kentucky, Dr. Ephraim McDowell successfully removed from Mrs. Crawford an ovarian tumor weighing twenty-two pounds. This was not a haphazard operation undertaken by a rash or ignorant surgeon. Dr. McDowell was a man of great natural intelligence, of dogged determination, of striking conscientiousness, of unfailing piety, whose early professional education in Virginia had been supplemented by two years' (1793 and 1794) study in Edinburgh under some of the most famous surgical teachers of his time. He had undoubtedly been inspired by the enthusiastic prediction of one of his preceptors, Mr. John Bell, that ovarian tumors might some day be successfully removed, so that, fourteen years later, when Mrs. Crawford, whose malady was hastening rapidly to a fatal termination, consulted him, he dared to advise the removal of the tumor, and to do it, in spite of the howling mob before his house, threatening his death in case of failure. Before operating he wrote out and put in his pocket a prayer: "O God! in performing this operation in the London hospitals had more than doubled."

Mason Warren writes: "The domain of surgery has been enlarged by admitting into the list of justifiable operations some whose severity would otherwise in most cases have prevented even the thought of attempting them."

Erickson writes, in 1878: "During the last thirty years the actual number of operations performed in hospitals has enormously increased, and probably in a

¹⁴ Boston Medical and Surgical Journal, October 15, 1896.

a case of attempted ovariectomy published in the October number of the *Edinburgh Medical and Surgical Journal*, 1824. In 1825 Mr. Lizars further attempted ovariectomy three times, with so unsatisfactory results that the operation was discountenanced in Scotland, and was not repeated for twenty years. He was, however, the first to do the operation in Great Britain. Meanwhile Dr. A. G. Smith, of Danville, Ky., did the operation unsuccessfully in 1818, and successfully in 1823; Dr. Nathan Smith, of Yale College, successfully in 1820 at Norwich, Vt.; Dr. J. A. Gallup unsuccessfully in 1824 at Woodstock, Vt.; Dr. D. L. Rogers, of New York, successfully in 1829; Dr. J. C. Warren, of Boston, unsuccessfully in 1830.

Meanwhile, before his death on June 20, 1830, McDowell had operated thirteen times, with at least eight recoveries.

On the continent of Europe the operation had found but little favor. In Germany the first operation was performed by Chrysmar, of Isny, Württemberg, in May, 1819; but from that year till 1850 but 23 operations were done with only seven recoveries.

In France there was no operation until that by Dr. Woyerkowsky in 1844, and but three (with two successes) up to 1850.

From the "Table of Ovariectomies" published by Dr. W. L. Atlee in 1851, I obtain the fact that up to January 1, 1847, but about 150 operations had been performed in the world.

Just before this date the world had been electrified by the announcement of a discovery of more transcendent importance for the welfare of humanity than any that had preceded it in the history of the world. On October 26, 1846, Dr. W. T. G. Morton demonstrated the fact, that the fumes of sulphuric ether would render a human being insensible to pain, by administering it to a patient at the Massachusetts General Hospital in Boston, U. S. A., while Dr. John C. Warren excised a tumor from his neck without his experiencing the slightest sensation.

Luckily for the rapid dissemination of this announcement and its prompt adoption throughout Christendom, it came vouched for by surgeons of eminent standing and unquestioned integrity.

This event gave an immense impulse to surgery in general, not only for the reason that patients would submit willingly to the knife from the knowledge that the procedure that promised a chance of life or escape from protracted suffering, was absolutely free from the intense anguish which had previously attended all operations; but also for the reason that the time consumed in the operation had ceased to be an important matter, so that surgeons could dissect leisurely and carefully where they had formerly had to hurry through their task for fear that the patient would die of shock upon the table.

If this was true of surgery in general, how much more must it have influenced the performance of ovariectomy where the thought that their vitals were to be invaded by the knife of the surgeon must have appeared more terrible to the suffering women than the slow death to which they knew themselves to be doomed by the progress of the disease. While there may have been other women whose fortitude was as great as that of Mrs. Crawford, who, with a full understanding of the nature and hazard of the operation, and of its never having been performed before, accepted the risk and endured the torture, yet the majority

must have shrunk from the ordeal. The operator, too, must have needed all his nerve and skill to conduct an operation to a successful issue with the patient shrieking and writhing in agony. While I have been unable to discover that the ovariectomists of the day, in their reports, laid any stress on this new procedure as an important factor in facilitating their work, a notable spread of the operation is apparent in the ten years following this discovery.

Between 1847 and 1857 the number of operations increased rapidly but still in the hands of comparatively few operators. These were still chiefly in America and England. In the former the most determined operators were Drs. John L. and Washington L. Atlee, Peaslee, Burnham, Kimball and Dunlap; in England Drs. Clay, Bird and Baker-Brown. Up to the end of 1856 there had been only 97 operations in America, with 54 successes; in England 123 operations, with 76 successes; in Germany 47 operations, with only 13 successes. In 1850 there was a discussion of ovariectomy at a meeting of the Royal Medical and Chirurgical Society on November 12th, in which there was general complaint that the incomplete and unsuccessful cases had not been reported. The consensus of opinion was strongly condemnatory of the operation.

The years 1856 and 1857 were made famous in the annals of ovariectomy by the renowned discussion in the Academy of Medicine of Paris. Up to this time ovariectomy had been completed but four times in France, twice successfully. All the disputants but one—Cazeaux—condemned ovariectomy as a rash, unjustifiable procedure.

We now come to the "Revival of Ovariectomy" as it was called by Spencer Wells in the title of one of his introspective papers, his participation in which earned for him the name of the "Greatest of Ovariectomists." Before setting forth his share in this movement, I should feel called upon to dilate upon his early training where these data not to be set forth more fully elsewhere in this volume. Suffice it to say that when he settled in London in 1863 he had never seen a case of ovarian disease. His first incomplete attempt to remove an ovarian tumor was in December, 1857; his first complete operation in February, 1858; before the year closed he had done two more operations, both successfully; in 1859, 11 cases; in 1860, six cases; in 1861, 11 cases; after which the number increased at a rapid rate. The secret of his success did not consist in any special procedure, but by attention to a multiplicity of details which in the aggregate did a great deal to ensure recovery. Simple bandages for keeping the patient quiet supplied the place of an objectionable crowd of assistants. Every spectator had to declare that he had not made a post-mortem examination or been in a dissecting-room, or attended any case of infectious disease within a week. The room, bedding, clothing, sponges and instruments received the utmost attainable purification. The incision in the abdominal wound was shortened; the cyst was emptied before it was drawn out; extreme care was taken to prevent the entrance of ovarian fluid into the peritoneal cavity; and likewise to cleanse the cavity of all blood or fluid which had entered it.

The favorable results which he achieved by these details had far less effect in reversing the verdict of the profession, than the absolute openness with which he

operated in the presence of authorities, and the perfect honesty with which he published every case, successful or otherwise, doing his full duty by stating "operated in the presence of A, B and C," and the exact time and the conditions under which every fatal case terminated. Every result could be corroborated by unimpeachable witnesses and records. By this means he silenced the criticisms passed upon previous operators, with more or less justice, of concealing their unfavorable results. Under these conditions public opinion rapidly changed in England. In February, 1859, he reported his first five operations to the Royal Medical and Chirurgical Society, and by 1860 the verdict of the profession was reversed. In 1862 he reported to the same Society his first 50 cases of ovariectomy. From this date his publications were numerous. In 1865 he published his first book "Diseases of the Ovaries: Their Diagnosis and Treatment," being a full clinical report of his first 114 ovariectomies. In 1872 he published a new book under the same title, being a full summary of the subject with tables of 500 cases: in 1882 another, entitled "Ovarian and Uterine Tumors; their Diagnosis and Treatment," and lastly, in 1885, another, entitled "The Diagnosis and Surgical Treatment of Abdominal Tumors."

Of course, during the early years of this period other operators did not fail to follow his lead, notably Thomas Keith of Edinburgh, who vied with his acknowledged master in painstaking attention to the details of the operation and absolute honesty. The relations of these two great men was admirable in their appreciation of each other. Writing in 1863, Keith says: "No one has done more than Mr. Wells to improve the operation, and simplify its after-treatment; and it gives me pleasure to acknowledge that when I commenced these operations I took him for my guide." In 1884 Wells says: "Keith was one of the first to follow me, and did more than any one else at that time to assist in the revival of ovariectomy. I had done eight cases when he began, and ever since we have gone on, side by side, very friendly rivals, assisting each other, comparing notes, not always running on the same track, but always equally anxious to perfect the operation. You all know how wonderful his success has been. Some of his later cases of the removal of uterine tumors are unsurpassed as surgical achievements."

It was my fortune to witness many of Mr. Wells's operations in the spring of 1873, and in some instances to assist him. I shall never forget the impression his strong personality made upon me, and the admiration his honesty and skill inspired. As an instance I especially recall being his sole assistant in an operation in Birmingham, when, the moment his first incision laid bare the surface of the tumor, he stopped and said in a low tone through lips which never seemed to move, hardly to open, "Hullo! what's that?" With two fingers he explored the tumor and the abdominal cavity, then, turning to the patient's physician who had maintained from the outset, contrary to Mr. Wells's opinion, that the tumor was an enlarged spleen: "Doctor, you were right, it's the spleen." After a moment's consideration he said, "I think I'll take it out," enlarged the incision and took it out. Unfortunately the woman died on the fourth day. Two weeks later when I presented a letter of introduction from Wells to Keith in Edin-

burgh, the latter had hardly glanced at my card when he said "I have been waiting to see you; now sit right down and tell me all about the removal of that spleen." I make no apology for introducing this personal episode, because it illustrates better than words the character of these two great ovariectomists, and discloses the secret of their successes and of the confidence which they inspired.

The influence of Spencer Wells's work and publications was not long in being felt on the continent of Europe. In France only three operations, all fatal, were performed between 1857 and 1862. In the autumn of 1861 Nélaton visited London purposely to witness the operation of Wells and Baker-Brown; returning full of enthusiasm, he lectured at the Hôpital des Cliniques on October 25th upon the five operations that he had seen, and appealed energetically to the surgeons present to lay aside their exaggerated fear of this operation. His influence, together with the appearance of several publications, led to the performance of 14 operations in 1862. Koeberlé, of Strassbourg, did his first operation on June 2, 1862. Péan did his first in November, 1864. Up to April 1, 1867, there had been 116 reported cases, with only 47 recoveries.

In Germany there had been only 55 operations, with 40 fatal results, up to 1863. From 1864 to 1867 there were 125 operations with 65 deaths.

In Austria the first operation was in 1866; and there were only 12 operations with 11 deaths up to 1871.

Meanwhile, in America the operators were as active as in Europe, but their work had not the influence upon the rest of the world as was its due, probably for the reason that the operators were to a great extent country surgeons who were not as ready with the pen as with the scalpel, so that the work of each was but little known beyond his immediate field of practice. A notable exception was Dr. Washington L. Atlee, of Philadelphia, who bore the brunt of the contest to overcome the prejudice against the operation. Up to 1855 Dr. Atlee had done 31, and before his death in 1878, 387 ovariectomies. He was ably seconded by Dr. E. R. Peaslee, of New York, who did his first operation in 1850.

Spencer Wells performed ovariectomy over 1,200 times, reducing his mortality with every successive hundred cases. He lived to see the old dread of opening the peritoneal cavity banished from surgery, to see the operation of ovariectomy accepted all over the world; and he must have taken intense delight and pride in the thought that to his labors, more than to any other man, was this revolution attributable. He died of apoplexy in France on January 31, 1897, three days before his seventy-ninth birthday. With characteristic independence his body was, by his request, cremated at Woking, England.

Before alluding to the final great innovation that has stimulated the practice of all surgery, but more especially that of abdominal surgery, I must ask you to glance with me for a moment at the studies which led to this great step.

Louis Pasteur, born on December 27, 1822, was in 1854 nominated to be Dean of the Faculté des Sciences at Lille, France, and desiring to be of use to one of the principal industries of that Department, which was the fabrication of alcohol from beet root and from corn, resolved to devote a part of his time to the study

of *fermentation*. To make clear the profound significance of this word I venture to transcribe a paragraph from the life of Pasteur by his son-in-law:

"All that has lived must die, and all that is dead must be disintegrated, dissolved or gasified; the elements which are the substratum of life must enter into new cycles of life. If things were otherwise, the matter of organized beings would encumber the surface of the earth, and the law of the perpetuity of life would be compromised by the gradual exhaustion of its materials. One grand phenomenon presides over this vast work, the phenomenon of fermentation. But this is only a word, and it suggests to the mind simply the internal movements which all organized matter manifests spontaneously after death, without the intervention of the hand of man. What is, then, the cause of the processes of fermentation, of putrefaction, and of slow combustion? How is the disappearance of the dead body, or of the fallen plant to be accounted for? What is the explanation of the foaming of the mush in the vintage cask? Of dough, which abandoned to itself, rises and becomes sour? Of milk which curdles? Of blood which putrifies? Of the heap of straw which becomes manure? Of dead leaves and plants, embedded in the earth, which transform themselves into soil?"

The ancient theory to account for this mystery received the endorsement of Liebig and was enunciated by him as follows: "The ferments are all nitrogenous substances—albumin, fibrin, caseine; or the liquids which embrace them, milk, blood, urine—in a state of alteration which they undergo in contact with the air.

"The oxygen of the air is, according to this system, the first cause of the molecular breaking up of the nitrogenous substances. The molecular motions are gradually communicated from particle to particle in the interior of the fermentable matter, which is thus resolved into new substances." Living organisms had been observed by a few investigators in certain fermentations, but their presence was regarded as a purely accidental fact, which, instead of favoring the phenomenon, was injurious to it. Without going into the details of his experiments it suffices to say that from his first investigation of the lactic fermentation Pasteur was led to take an entirely different view. In this fermentation he recognized the presence and the actions of a living organism, which was the ferment. By ingenious experiments he established these facts beyond question and presented them in a memoir to the Academy of Sciences in 1857. The question of spontaneous generation next engaged his attention, and in 1860 he won the prize offered by the Academy of Sciences for the best essay on this question, his conclusion being, "spontaneous generation is a chimera."

In 1861 he discovered that the agent of butyric fermentation consisted of little, moving, thread-like bodies; also that a microscopic organism was the cause of ammoniacal decomposition of the urine; in 1863 he established the fact that the bodies of animals in full health are sealed against the introduction of the germs of microscopic organisms; in 1863 he discovered the vibrio of putrefaction.

The publication of these facts brought the attention of Davaine back to observations which he had made in 1850 without appreciating their significance, when he was investigating splenic fever with Rayer: "That in the blood of splenic fever patients, are found little thread-like bodies about twice the length of a blood-

vessel." These observations, when repeated by Davaine in 1863, were vigorously assailed, and the doubts thus raised were not finally refuted until Pasteur demonstrated the correctness of Davaine's assertions in an unanswerable manner. It is manifest that Pasteur's researches on the part played by microscopic organisms in fermentation had changed all the preconceived ideas about viruses and processes of disease. A great scientific fact had been established that a virus might consist of microscopic beings. The virulence was due to their life.

In 1865, an apothecary, Lemaire, published the researches that he had been conducting for many years on coal-tar and its most important ingredient, carbolic acid. By extensive experiments on higher and lower animals and plants, he established the fact that this chemical material destroyed all organic life in a very short time. He asserted that the changes which were observed in wounds were likewise produced by living organisms; that suppuration was produced by germs that entered wounds from the air and then multiplied. "If this theory is correct," says Lemaire, "it must be possible to prevent suppuration by treating fresh wounds with an emulsion of coal-tar or with carbolic acid."

Joseph Lister, in Edinburgh, Scotland, first made a practical application of these discoveries of Pasteur and probably of those of Lemaire. His indebtedness to the former he acknowledged. In 1867 he published a paper in the *Lancet* setting forth his first crude methods of excluding germs from wounds. "If," as he said correctly, "all decompositions are caused by external germs, those changes, so often observed in wounds, with their harmful effects, must be produced by germs entering the wounds from without. By exclusion of these germs all decomposition in wounds must be capable of prevention. As these germs are everywhere present, in the air, in water, on the instruments, on the dressings, care must be exercised to destroy them by some suitable germicidal means, such as carbolic acid, before the materials come in contact with the wounds." On the basis of these theories he worked out a method of treating wounds into the minutest details, tested them in the Edinburgh Infirmary, and, after proving the correctness of his views by practical demonstration, he presented them for the verdict of the medical world. Despite the force of his evidence and the enthusiasm of his advocacy, it took many years to obtain a recognition of so profound a reversal of all antecedent principles on which surgery had been based. In 1873 I saw Lister operate, but swayed by the scoffings of all my preceptors whose views I accepted unquestioningly, I failed to grasp their significance. Notwithstanding the success of Lister's claims and methods it must be remembered that the actual germ was not recognized and described until 1878 when Pasteur discovered that the vibrios of acute septicemia reproduced themselves by spores.

Of course, it was at once seen by ovariotomists how vital this innovation of Lister's, if correct, would be in affecting the results of their work. Among the earliest to study Lister's methods was his fellow-townsmen and friend, Thomas Keith, who from 1869 to 1871 used a two-per-cent. solution of carbolic acid in sponging out the peritoneal cavity, antiseptic ligatures, and had all his instruments rubbed with carbolic acid, etc., without any improvement, however, in his results, but rather the reverse. He consequently gave

up the method in ovarian work, trusting entirely to care and cleanliness. After the technique was improved by the addition of the spray, he returned to the antiseptic method in 1876. Before this his mortality in the last 100 cases was under ten per cent.; in the 50 operations performed subsequently under the spray he lost but two patients, only four per cent. More striking results were gradually announced by other surgeons, but the Germans presented the most conclusive argument in favor of Listerism in a letter to Mr. Wells from Olshausen, in 1878, giving his results and those of Esmarch, Hegar and Schroeder: without spray a mortality of 50 cent. in 65 cases; with spray a mortality of 20 per cent. in 155 cases.

By 1880 the antiseptic method was pretty generally adopted, the world over, for abdominal operations, with a reduction of the rate of mortality, from the outset, of more than fifty per cent.

All honor to Sir Joseph Lister for introducing the most important modifications of our surgical methods since the world began.

I have thus far confined my story entirely to a consideration of abdominal surgery for the purpose of the removal of ovarian tumors, because the whole development of abdominal surgery originated in ovariectomy. It now behooves me to call your attention to the other purposes for which the abdominal cavity is invaded. First among these is for the removal of fibroid tumors of the uterus. The earlier operations for this purpose were done when fibroids had been erroneously taken for ovarian tumors. In 1885 Dr. Thomas Keith dedicated his monograph on "Hysterectomy" to our fellow, Dr. A. J. C. Skene of Brooklyn, in the course of which he says: "I offer you something that is not mine but is of American origin; for though hysterectomy may have been performed by others by misadventure, if I greatly mistake not, the first case of uterine fibroid, diagnosed before operation, was removed by my old friend Dr. Kimball, of Lowell." This is true.

It is not my purpose to follow the development of hysterectomy for fibroids; for though it presented special difficulties in its earlier days, it followed ovariectomy and was the first harvest from the knowledge acquired through the latter operations. Its history is very similar to that of ovariectomy and is largely written by the same hands: Kimball, Burnham, the two Atlees, Peaslee and Thomas in America; Brown, Bantock, Keith, Savage, Wells and Thornton in England; Hegar, Billroth, Kaltenbach, Schroeder in Germany; Koeberlé and Péan in France.

The fact established by ovariectomy, with the aid of antiseptics, that the peritoneal cavity could be opened with impunity, has since led to operations upon all the other organs contained therein. During ovariectomies the intestines were accidentally wounded, the rents were sewed together with perfect restoration of function, thereupon the abdomen was opened for the cure of fecal fistulae, for the removal of the inflamed appendix, for the relief of strictures of the intestines whether by peritoneal bands or cancerous invasion of its canal, for the removal of gangrenous portions of intestines in inguinal or umbilical herniae, to repair perforations by gunshots or by stabs, etc. Other organs in the abdominal cavity, enlarged by new growths or inflammations, were removed, such as the spleen, the kidneys, etc.; cancers of, or foreign bodies in, the stomach, gall-stones, calculi in the kid-

neys and ureters were excised; floating kidneys were anchored; tumors of the liver were cut out; diseased Fallopian tubes were tied off; tubercular peritonitis was found to be curable by simple abdominal incision; Cæsarean section and Porro's operation were performed with marvellous success; the cancerous uterus was excised; the adhesions fixing a retroverted uterus were torn asunder and the displacement corrected by stitching the fundus to the abdominal wall, etc. The field of the surgeon was thus immensely extended; previously his work had been confined chiefly to the outside of the body, then he did not hesitate to explore every recess of the abdominal cavity and its contents. He did not stop there, when he had learned that he had means to enable him to enter with impunity one of the great cavities of the body, he applied the knowledge and skill thus acquired, to devising means of attacking the other cavities. He found that he could open the great joints without danger of entailing subsequent immobility; to reach the thoracic cavity he did not hesitate to excise segments of the ribs; and finally, most miraculous of all, after locating the diverse functions of different parts of the brain, he bored through the cranium and lifted depressed fragments of bone that caused epilepsy. He evacuated collections of blood or pus, or removed new growths or foreign bodies that by pressure upon the nerve centres were producing paralysis of distant limbs or impairment of intellectual processes. All this and much more is the outcome of ovariectomy.

So we find ourselves at the end of the nineteenth century with less reason to dread the opening of the abdominal cavity than our immediate predecessors had to dread even minor operations upon the body and limbs. The benefit of this advance to the individual and to the race is manifest; but I would beg you to pause a moment and consider with me if this *furia operativa* has not gone too far — whether the time has not come when we must take an account of stock and differentiate more closely, in the individual cases, whether a removal of the whole or a part of the generative organs of a woman is the only method available for the cure of the diseases or injuries to which these organs are liable, and, furthermore, whether such removal, while attended with but trifling immediate risk to her life, is to be regarded as the only resource which nature, supplemented by art, has of restoring a suffering woman to comfort and health. We have been told abundantly of the millions of operations done; we have had spread out before us long series of cases in which the uterine appendages have been removed, or the uterus itself extirpated; but have we learned what the future fate of these women has been. We know that fame and fortune have come to those among us who have been most successful in our ratios of mortality after operations; we do not know how many of the surviving patients have cause to bless us for our technical skill. No one can deny that for the race it is an unmixed evil to have a large percentage of our women, still in the childbearing age, rendered suddenly sterile beyond recall. No one can deny that it is an opprobrium on the healing art that we must remove organs, even though unessential to life, because we cannot cure them. Is not our suddenly acquired ability to do these operations leading us too far and too fast in sacrificing organs and functions that might be preserved with benefit to the race, and without detriment to the individual? A paragraph from the

posthumous work of Léon Lefort, as published by Dr. T. C. Minor in the *Cincinnati Lancet Clinic* is much to the point:

"What are the causes of the *furia operativa*, that more cruelly overwhelms foreign than modern French surgery? The first and most legitimate is the absolute and firm confidence—let us add, even blind confidence—that all surgeons seem to have who believe in antiseptic precautions. The general condition, diathesis, psychical or moral influence peculiar to the patient, count for nothing; all the danger is from atmospheric germs; and providing they can prevent the entrance of such, it is believed that any one may open a belly or an articulation without the slightest danger. What good is it to waste time by a long and tiresome course of medical treatment, when by an operation, whose evident dangers are refused recognition, one can cure quickly? What good is it to worry over such a trivial thing as a diagnosis, when by merely cutting a patient open one can determine whether a suspected disease exists or does not exist?"

"A so-called surgeon recently expressed himself as follows: 'My patient was aged nineteen years; she suffered from her bowels, and I could only establish my diagnosis by the touch; and, as she was a virgin I feared to deflower her by making a vaginal examination. I thought it much preferable to make an exploratory incision in the abdomen, and found she had no disease.' Think of it. To prefer opening the abdomen to the vaginal touch, when by very little precaution the touch may be practised, while wholly respecting the hymen. This is modern gynecology with a vengeance!"

It daily falls to my lot, as one who has not been carried away by the present *prurigo secandi*, to see those women who have been operated upon by my more venturesome colleagues, and to find that results are by no means as uniformly successful in relieving symptoms as the operators are wont to report.

The cessation of function in the generative organs of woman has always been rightly regarded as a period fraught with serious and protracted disturbances of the general system. It is contrary to reason to suppose that the artificial arrest of these functions by the removal of a part of the system can be practised without even greater peril than when nature effects this end. The natural menopause is attended with a profound derangement of the nervous system, not infrequently with impairment of the mental faculties; it is followed commonly by an excessive accumulation of adipose tissue; it is uniformly followed by an atrophy of the whole genital tract, with diminution in the calibre of the vagina, which renders the woman incapable of fulfilling her marital duties. All these sequelæ of the natural menopause are likely to occur, and have, in my experience, occurred, as a result of the operations which we are now considering. How much more pronounced are these ultimate effects likely to be in a woman in whom the change of life is artificially produced in the early years of her genital life when the nutrition and other functions are in full vigor. Of course, if the mishaps attendant upon childbearing and the diseases invading the sexual organs are incurable by other means than the surgeon's knife, exposure to these sequelæ of the menopause may be the lesser of the two evils; but let us not operate without an eye to the future as well as the present. We are all aware that the great dread of all women, cancer, is likely to

occur during the climacteric years; we do not know whether the cessation of that function is the determining cause of this greater prevalence, and whether we may expect a like effect to attend, or follow a menopause brought about artificially at an earlier age.

The time has come when another almost untrodden field is spread out before us. I mean investigation and experiment to see if methods cannot be devised for treating diseased tubes and ovaries, after the abdominal cavity is opened, without complete extirpation. A slight attempt in that direction was reported to this Society in 1893, by Dr. Polk, when he described operations in which only portions of the ovaries were removed. This is looking in the right direction. Should we not be experimenting to see if we cannot evacuate serum or pus from an occluded Fallopian tube without sacrificing it and its corresponding ovary, as is the custom? Should we not familiarize ourselves with nature's method of cure of an inflamed tube. I recall a case in which I opened the abdomen two years ago for the relief of retroversion with adhesions of the fundus to the rectum. I found both tubes occluded at their fimbriated extremities and containing a slight amount of fluid, which I assumed to be serum, not pus. Against the protests of my two assistants, I left the tubes untouched on the ground that they had been healed by a process of nature, and contented myself with stitching the fundus to the abdominal peritoneum. The woman has been perfectly well ever since, and has, I believe, a much better chance of a comfortable existence than she would have had, if I had removed both tubes and ovaries, as I should have done had I been of a less conservative temperament.

I do not expect the above remarks to carry conviction to those who are elated with their surgical achievements; but they are conclusions that I have reached and speculations in which I have ventured to indulge, after twenty-four years of special practice in which I have done my fair share of operating, and I trust they will be deemed worthy of your consideration.

PRESIDENT'S ADDRESS.

DELIVERED BEFORE THE AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS, WASHINGTON, MAY 4, 1897.

BY FRANCIS SEDGWICK WATSON, M.D., BOSTON.

GENTLEMEN:—Last year I lost, through a misunderstanding on my part, the opportunity to thank you for the privilege you then gave me of being your presiding officer at this meeting.

I beg to offer you my excuses for the mistake, and to ask you to accept my thanks now, which, believe me, are not the less warm because of their being delayed.

The programme promises so much that is important and valuable, that I am reluctant to occupy even a few moments in speaking of other matters.

I will ask your permission, however, to say just a few words.

I think it must have been a matter of surprise to some of the least conservative of us even, to have seen the large amount of new material annually contributed by our members to this branch of surgery—a field thought to be already pretty thoroughly explored and cultivated before this Association was formed.

I forget which notable surgeon of Europe it was that made the rash assertion, some ten or fifteen years ago, that the limits of operative surgery had been reached, and that in the future we must look for advance along the lines of perfected technique and the appropriate selection of cases only. In the overwhelming refutation that overtook this dictum, the workers in our special branch of surgery have taken their full share, and we have only to look at the record of the work of the members of this Association during the last ten years, to feel that we have well sustained our part in the general progress.

This leads me to speak once more of the loss I think we sustain in not having the Transactions of the Association published.

I remember a remark of Mr. Treeves to the effect that he had derived more benefit from records of well-reported cases than from any medical essays that he had ever read. In the main I agree with this view, which of course was not intended to minimize the importance of purely scientific work, and believe that the clinical experiences of such observers as those constituting this Society, would, if collected into volumes of Annual Transactions, be the best books of reference on the subject to the profession at large, as well as a source of satisfaction to ourselves. I earnestly hope that the Association may see its way to doing this in the future.

There is another suggestion I would like to make, which, if adopted, would, I think, give an additional interest to our meetings, and this is, that each year we shall take some special subject for individual investigation, and report upon it at our next annual meeting.

Each year I look forward to meeting my *confrères* here with the certainty born of repeated experience, that I shall hear the results of work that is earnest, thorough, and very often original; and not the least among the attractions which I anticipate, and which have drawn us so strongly together, and maintained the vitality of the Association, and given us so much pleasure in its meetings, has been the absence of all disagreeable controversy, and the high standard of professional courtesy which has characterized our relations and debates, which I trust will never change.

Permit me to welcome most cordially each and all of you, and to proceed without further preface to the work before us.

TENDENCIES IN MEDICINE.¹

BY J. M. DA COSTA, M.D., LL.D.

It is expected of the President of your Association that he offer some remarks as introductory to the scientific papers that are to occupy your attention, and every presiding officer has done so, expressing himself on subjects for some time in his mind or to which he has been recently giving heed. Thus, diversified and excellent addresses have been made, some treating of medicine and its aims in a broad, philosophical spirit; some reviewing its achievements; others giving most erudite and valuable historical information. In my turn I ask that you will indulge me if I present a few thoughts on what seem to me in our science the best tendencies of the day, as well as on certain causes that, with all the wonderful work being done, and

with the immense energy and industry of the devoted laborers in four continents, retard its still broader and steadier development.

The greatest advance of our time—it seems trite to mention it to such an assembly—is the ardent study of the causation of disease. Students have speculated in all ages on the causes of disease; but these have been, for the most part, half-hearted speculations, made so by the feeling of impossibility of reaching a conclusion, or dogmatic assertions that, believed in for a time, soon became of interest only to the curious searchers for fragments on the shelving beach of science. Now, the recognition of minute organisms, their study, their artificial culture and modes of growth, their secretions, their chemical characters, their likes, their antagonisms, have let us into the secrets of another world and are showing us the way in which infective maladies originate and the laws they obey. We are looking for infection in every disease; we are often keenly pursuing it where it probably does not exist; at all events, not in the shape of bacteria, which in our day we accept as a term almost synonymous with infection. A sense of causation, formerly deficient, has been replaced by a most acute sense, and by a desire for unremitting search. What is still greatly needed is, I think, an appreciation of how infection may light up slow processes and lead to structural complications, such as are found, for instance, in the exanthemata. We have also much to learn of bacteria that exist normally becoming abnormal in certain perverted conditions, either in manifold growth, as happens with the bacillus coli communis, or in character. What we consider the cause may thus be only the consequence of disease. The soil and its forces, too, are to be studied and critically examined.

But the power of this little, invisible world is mighty. It is told of Napoleon that he could never understand the fame of Cuvier. He spoke of him, with something like contempt, as only occupied with small things. Yet smaller things conquered even him, the great conqueror. It was the plague bacillus, not Sir Sidney Smith, that compelled him finally to leave Syria and give up his dream of subduing the East, like another Alexander.

Other than mere bacteriological work forms a most valuable part of the contribution of the laboratory to the investigation of disease, and in the last decade has placed this investigation on a much higher plane. The microscopical and chemical examinations of the secretions and excretions and of the blood have become our daily duty. The chemical examinations, which, dealing, as they may be made to do, with the constantly varying problems of life in disease, have been temporarily overshadowed by the ardor of bacteriological research, will, with widening fields, resume their former prominence. The time is indeed at hand in which, without the ready access to a laboratory manned by experts in all these lines, or the association with a trained laboratory assistant, no physician can do his patients, himself, or his science justice.

Closely connected with the laboratory investigation of disease, especially with its chemical investigation, is the study of the effects of the products generated by decomposition of albuminous matter, producing, when developed in the dead body, the substances known as ptomaines, when in the living body, as leukomaines. The recognition of these agents, so fre-

¹ President's Address delivered before the Association of American Physicians in Washington, D. C., May, 1897.

quently poisonous, is explaining many obscure processes, is leading to new and close scrutiny of others and to search after means of neutralizing their toxic influence. It is with pride that this Association can view the history of this branch of research, for the fruits it has yielded have been largely gathered by the efforts of some of its own members.

Another of the best results of the achievements of our time is seen in the effacement of the strict division between medicine and surgery, or rather in the recognition that there are no lines separating them, but lines becoming continuous, on which joint action proceeds. We see this in the whole clinical history of appendicitis and its progressive unfolding; the more the medical part is studied and rendered precise, the more exact become the indications for operation and the appreciation of the chances of this. The same may be said of abscess and of tubercle of the kidney; of the investigations of the character of effusions into pleural, or pericardial, or peritoneal cavity; and of many other well-known conditions that surgeons and physicians are now studying together. This new tendency is sure to counteract not only the excessive specialism of our day, but to give us once more broader physicians and surgeons, taking the keenest interest in each other's work.

One of the greatest improvements in our generation is in the much better appreciation and larger use of hygienic means, of systematic exercise, of baths, of regulated rest, of out-door life. Then, too, when medicines are given they are much more generally used singly, with a view to their direct effect, and not in excessive combination. Moreover, the substitution of extracts and of active principles for many of the nauseous drugs has taken away the terror and disgust with which medicines were regarded. It is, from a pharmaceutical point of view, at least, no longer a punishment to be ill. The satire of Molière is lost to the playgoers of our generation. The highly appreciated answer of the Bachelor of Medicine, when examined for his doctor's degree, that the remedies are always "Clysterium donare, postea seignare, ensuite purgare," would fall at present on totally unsympathetic ears; for now there are delightful capsules, and triturates, and pills of esthetic colors—"dear little pink pills," as I have heard them called, though the dear little pills happened to contain strychnine. And the boy of the period is not tempted to view an open window as the only means of getting rid of the hated bottle; he may, indeed, want to take too much of it, because, with all its potency, it is sweet and pleasant.

The tendency of our time is to endeavor to overcome disease, and not merely to observe and palliate its ravages. We are going back to the doctrines of our forefathers, abandoned for a time, because, with an expanding knowledge from the study of pathology, the means they possessed were found to be, for the most part, totally inadequate. Thus there was a period of nihilism and expectancy in therapeutics. But so-called rational expectancy is but a confession of impotency. Now, the tendency is once more aggressive. We are trying directly to choke or to subvert morbid action, and doing this partly through the old, transmitted remedies of former generations, but employed with a better understanding of their real qualities, partly by new agents furnished by chemistry and by constant research in other fields. Of the former, the freer and more scientific administration of digitalis

may be taken as an illustration; and the use of mercury, though in a different manner, is infinitely more prevalent than it was some years ago. To bleeding, too, I, for one, believe that we shall return; only it will be not the mere abstraction of blood perverted by disease, but there will be, with this, immediate attempts at the reconstruction of the blood by supplying it with the proper saline fluid and other ingredients. In the second class, the bromides, chloral, the nitrites and nitroglycerin are prominent, as is a whole group of antiseptic agents. Many of these—it is especially true of the nitrites—have come to us from the physiological laboratory. One of the most interesting attempts at radical therapeutics is the endeavor to counteract the bacteria of disease by substances that form in the body which neutralize their toxic products. This antitoxin treatment is brilliant and hopeful, and is being tried in many affections, pre-eminently in diphtheria, in tetanus and in erysipelas. It cannot be said that as yet it has led to any great results, though the evidence is decidedly in its favor in diphtheria. It seems scarcely worth while to push it in erysipelas—at least in erysipelas that the physician sees—for the mortality in this is, under any treatment, but very slight. How valuable the antitoxins will prove as preventives remains also to be solved. More productive thus far has been the use of attenuated virus, as for instance, in Pasteur's treatment of hydrophobia; the influence in cholera, in yellow fever, in bubonic plague, is now under keen observation. The effects on tuberculosis must be taken thus far as the expression of hope rather than of fact. The next decade will prove whether the x-rays, which are making such wonderful additions to diagnosis, will also have their therapeutic triumphs. In it, too, we may look for some striking developments of suggestion, not only as explaining mental and morbid processes—what more extraordinary and thought-starting, for instance, than the recently tested production of special cutaneous affections by it?—but also as a harnessed therapeutic force. All this is in the line of present investigation; and there will be much disappointment and wasted labor in particular points, but it is not too sanguine to believe that there will be also a solid outcome which will immensely advance scientific medicine.

There are, with all these tendencies of our day that work for good, some which, whether growing out of them or whether the exaggeration of old hindrances, have to be, in the interest of true science, strenuously guarded against. One that is very evident is the tendency to immediate generalization. The discovery of every new bacterium is supposed to instantly revolutionize the science of medicine, and is announced with all the air of the unexpectedness of genius. Fortunately or unfortunately, one may be discovered every day, and a man may thus find himself with three hundred and sixty-five opinions on the tenets of his art in the course of the year; but this would not daunt the enthusiasm of the insatiate generalizer:

"Ten thousand great ideas filled his mind,
But with the clouds they fled, and left no trace behind."

Fixity of opinion in medicine is a virtue, if the mind remain open to proof and is in sympathy with advance; and it is this freshness of mind, joined to a good judgment, through which is best estimated the true value of the many facts constantly discovered in

an advancing science like ours. Clinical medicine, indeed, must remain the final court of appeal for the purposes of the practitioner of medicine. Before that court will come and be listened to with sympathetic interest, as eloquent advocates, those who are presenting the claims of special studies. But these must be well supported and judged in their bearing on the whole before new laws are laid down. And we see that the more we investigate and the more we know, the more will old questions assume different aspects, the more they will have to be retested; there is no finality—there can be none—in medicine. When the last word is spoken we shall have a perfect science; until then there must remain for us a certain amount of empiricism, especially in treatment.

There is no doubt that, considering the amount of work done and recorded, medicine—especially clinical medicine—would be much more advanced if the records were differently made, and were not so vague as they often are. What is more provoking than to see constantly such loose statements as this: "The examination was negative." Negative as to what? If applied to the action of an organ, as to what part of its action? If to secretions, to what part of their constituents? How much easier to say, even if it have been an incomplete examination, for what exactly they were investigated, and how much more certain to be of use for comparison in similar cases. Worse still is it with the records of treatment. This is an ever-recurring expression: "The usual treatment was employed." I saw this in a recent volume of *Transactions* with reference to the congestion of the lungs in typhoid fever. What is meant? Is there such a thing as a fixed treatment for it the world over? It might mean dry cups to some; ammonia, turpentine, digitalis, or yet different things to others. Then the utter absence of mention of doses makes it impossible to say whether any remedy was fully tested, or to compare its action when given in small or in large quantities.

For very many purposes records, as published, are valueless; in truth, they impede progress, and a little care would make it otherwise.

Then there are records which, made even to the full limit of industrious exhaustion, are so badly and confusedly presented that they bury themselves from the start. A little more time spent on their expression might make them absolute and convincing. It would be indeed well if in all our professional literature there were something more of the learning of the scholar and the clearness of the literary artist; men who followed the master, Harvey, in other points besides profound and productive research. A few more Watsons and Pagets, Trousseaus and Hyrths would make knowledge easier to obtain, more constantly with us, forming much more a part of our daily life and application. It is true that if, in our science, we must choose between profound inquiry and its clear enunciation, we shall choose the former. It is a pity, and it is unnecessary, that there should be any occasion for a choice. The French with their lucidness in scientific matters, set all other nations an example. The countrymen of Goethe, foremost in investigation, following his avowed contemptuous indifference to style, are the greatest sinners against clearness and vivid expression. They evidently believe in the reverse of the thought with which Johnson excused the inaccuracies in Goldsmith's "Animated Nature," that, if he once began to make

experiments, life would be too short for him to get his book written.

One more tendency of the day let me notice, which is not for good, and undoubtedly retards progress. It is the excessive publication of half-knowledge, of doubtful fact, and of loose inquiry. The propensity of authorship is an old disease, but it has assumed a development commensurate with the prodigious development of everything else in the age in which we live. It is harmless in journalism, less so in literature, but positively dangerous in science; for it fills this with immature or false observation, and takes the time of others to remove the obstructions placed in the stream of knowledge. With some, want of sufficient training leads to it and absence of inquiry into what has been already ascertained; in others, it proceeds from a girl-like genius that, in place of letter-writing, pours itself out in medical periodicals, fascinated by penning sentences full of pseudo-scientific commonplace. It is far from being a disease only of the untried or ignorant; famed workers, too, may succumb to it, listening, perhaps, to the entreaties of friendly and sleepless editors. Who knows that it is not, after all, a physiological function, giving full play to brain-centres in very rare use—centres situated in what Oliver Wendell Holmes has called the idiotic area of the brain?

But whatever the retarding influences, they are not to any extent checking the onward course of medicine. The numerous inquiries, the keen experimentation and close research, the general thoughtfulness, are developing a resistless scientific method; resistless because it is true. Medicine is no longer an art founded only upon empirical observation, no longer a purely deductive science; it is also becoming an inductive one. The great body of the community is touched with friendly interest in watching its growth. With the advance of the scientific method special systems are crumbling; future ones are impossible. There can be no more pathies; the general intelligence will prevent it, for educated men are recognizing the broad base on which medicine is resting, and that truth is sought in it by the same means that are used in physics and in the highest development of other sciences. In our midst with all this, conviction is becoming clearer, purpose waxing more resolute. We see, without pang, castles which have crowned rocks being turned into dismantled memories, because we know that something stronger, that will defy all time, will stand ultimately on the old commanding sites. Every one of us must work until he discovers in his work his true self, and then aid with what he finds he can do best in helping all. With every one of us there is a mission to assist the general advance.

MEDICAL BADGES.—Russian doctors, according to the *New York Sun*, are hereafter to wear as a sign that they are legally qualified to practise, a silver oval plate an inch and a half long by an inch wide, on which is a design of two intertwined serpents. The object is to increase the safety of the wearer in the less civilized parts of the country. Russia borrowed the idea from Chicago, according to the *Journal of the American Medical Association*; as badges indicating their calling have been worn by physicians in that city for over a year.

PURULENT PERICARDITIS FOLLOWING PNEUMONIA.

PERICARDOTOMY; DRAINAGE; SUBSEQUENT EMPYEMA; OPERATION FOLLOWED BY ERYSIPELAS AND AXILARY ABSCESS; RECOVERY.

BY F. C. SHATTUCK, M.D.,

Professor of Clinical Medicine, Harvard University; Visiting Physician to the Massachusetts General Hospital;

AND CHARLES B. PORTER, M.D.,

Professor of Clinical Surgery, Harvard Medical School; Surgeon to the Massachusetts General Hospital.

E. W. C., twenty-six years old—of good habits, family and previous history, and of rather slight build—came down suddenly October 22, 1895, with general malaise. Physical examination was negative, and everything pointed to the diagnosis of influenza except a white-cell count of 17,900. There was no rigor, only chilly sensations.

October 25th. The diagnosis was established by the development of consolidation at the right lower back, extending forward through the axilla into the right front in the next few days.

October 28th. A loud friction râle, accompanied with pain, appeared over the whole cardiac area. White cells 26,400.

October 31st. Pericardial friction very faint, but no effusion could be detected.

November 2d. The pneumonia seemed to be clearing in a measure; pleural friction was heard in the left axilla; pericardial friction had disappeared.

November 6th. For the first time signs of notable pericardial effusion were detected, the heart sounds being faint and dullness extending half an inch to the left of the left nipple.

November 9th. Signs indicate a diminution in the amount of pericardial effusion. Fine crackling râles in left axilla.

November 14th. Pericardial effusion has increased again. Dullness one and one-half to two inches beyond left nipple.

November 18th. Nausea and vomiting rendered rectal feeding necessary. Paradoxical pulse. White count 12,950.

November 22d. Paradoxical pulse very marked. Condition critical. On consultation with Dr. E. G. Cutler, the pericardium was aspirated in the fifth intercostal space, about one and one-half inches to the left of the left nipple, and 16 ounces of sero-purulent fluid were removed—specific gravity 1.021, albumin one-fourth per cent., cultures show pneumococci. The pulse and stomach showed marked improvement after the aspiration. The reason for tapping in the above place will be set forth in a paper soon to be published.

November 23d. Pulse irregular and weak; temperature steadily rising the last few days; respiration irregular, with a suggestion of the Cheyne-Stokes type; dyspnea in irregular attacks; slightly delirious.

November 24th. The pericardial effusion was again fully as large as before the aspiration, and it was evident that nothing but incision and free discharge of the sac could save the patient; and, upon consultation with Dr. C. B. Porter, operation was decided upon and immediately performed.

At the consultation it was decided to approach the pericardium at the point where aspiration had

previously been done. A curved incision was made, exposing the fifth interspace at the left of sternum. Incision carried down between ribs, and pleura was opened one and one-half inches to the left of the sternum, in the fifth interspace. The aspirating needle was introduced through the first opening, and purulent serum escaped under considerable tension. Pericardium seized with forceps and opened. A stream of purulent fluid gushed out, spurting 12 to 18 inches above patient, especially on any expiratory effort. The effect on the pulse was a striking improvement (observed by Dr. M. H. Richardson) in quality, tension and volume. Amount of fluid estimated at about one quart. Pericardium douched out with sterile salt solution, and two soft rubber tubes put into pericardium, which was first secured by four silkworm-gut sutures that passed through muscles, and two carried through the skin. Absorbent dressing. Enema: brandy, one ounce; coffee, three ounces; digitalis, twenty minims. Pulse greatly improved after operation, but no immediate effect on respiration was noted. Dressing changed after eight hours, a large amount of discharge soaking dressing (not foul). Fluid from pericardium contains fibrin flakes. Cultures show pneumococci. Pulse after coming out of ether 130. Sleeps four to five hours, with one-eighth of a grain of morphia. Breathing easier. Pneumothorax present. Tympany at top of left chest, with absence of respiration. Supplementary respiration right lung. Liquids, two ounces every hour; oxygen, every twenty minutes for three hours.

November 25th. Large amount of discharge during night saturating a large dressing. Siphon tubes arranged to collect discharge. The two-and-fro suction of air, apparently into pleura, has ceased, and tissue is close around tubes.

November 26th. Tubes work well. Amount of thick pus collected from them eight ounces. Pericardium washed out with normal salt solution. The tube out of which the pus does not drain was selected as the one through which to put the salt solution. The outflow was immediate through the other tube. The amount injected was measured and compared with the amount coming out, thus any danger of distending the pericardium was obviated. Washings very thick. Does not disturb patient.

November 27th. Washed out this morning, condition better. Not as stupid. Pulse better. Taking liquids, 40 to 60 ounces daily. Brandy, 12 to 15 ounces. Somnolent. Perspiring freely about face and neck. Vomited twice. Wound about tubes tight. Pneumothorax less. Respiration heard fairly over left apex, with some râles. Loud pericardial friction. Respiration easier, 40. Pulse 140, fair, irregular.

November 28th. Washed out this morning at 10 A. M., 8 P. M. and 12 P. M. An attack of dyspnea in the afternoon. Amount of pus collected in last twenty-four hours, two ounces and one drachm. Washings contain many shreds and are rather thick, although they clear much more quickly than when washings were started. Nutritives omitted. Strychnia, one-fortieth of a grain every four hours.

November 29th. Air leaks in around tubes and destroys siphonage. Washed out at 9 A. M. and 3 P. M. A large number of flakes washed out. Washed in through both tubes to-day. Washings come clear very quickly. Has drained very little since morning.

November 30th. Washed out three times. Wash-

ings quite clear, few flakes. Tubes removed, and larger one shortened one-third and replaced. Heart's impulse can be felt with tube. Slight discharge on dressing. General condition of patient much better. Respiration irregular. Dyspnea, with tossing about of head. Sleeps in naps. Delirious at times. Takes liquids, 60 to 80 ounces, and brandy 15 ounces in 24 hours. Pneumothorax increasing, no respiration at left apex. Heart dulness not distinguishable. Some abdominal distention relieved by enema.

December 1st. Tube shortened. Discharge slight. Pericardium washed out t. i. d. with salt solution at 110° F. Feels better after dressing.

CHART I.—Pericarditis.

December 2d. Respiration and pulse the same. Restless, muttering delirium. Sleeps poorly in naps. Liquids fifty ounces in twenty-four hours, with toast and eggs. Brandy, ten ounces. Lungs almost flat over whole left back. Respiration relatively diminished, also fremitus. Right lung, supplementary respiration, some bronchitis. Pericardial friction over heart area. Metallic tinkling heard at left apex. Air sucked in and out of chest through wound.

December 3d. Washings clearer. Slight discharge.

December 4th. More delirious. Occasional Cheyne-Stokes respiration. Semi-comatose at times. At 2 A. M., one-eighth of a grain of morphia. This morning had an attack of acute collapse. Pulse weak, irregular, hardly perceptible. Patient cyanosed, skin

clammy. One ounce of brandy subcutaneously. Digitalis, twenty minims. Oxygen, heaters. Slowly rallied. At 10 A. M., fifteen minims of digitalis subcutaneously. Chest: left side flat, with diminished fremitus and respiratory sounds. Aspirated in fifth and seventh spaces in back. Six ounces of yellow serum obtained with a specific gravity of 1.020, albumin one-half per cent. Considerable pus in serum, but less than in pericardial fluid. Respiration a little easier since tapping. Stitches all out of wound. Small blind sinns sealed with rubber protective.

December 5th. Tube omitted. Opening into pericardium closed with gauze. Removed t. i. d., and

CHART II.—Empyema.

cavity washed out. Sleeps quietly. Less delirium. Easier respiration. Pulse better. Looks better. Chest: pneumothorax, metallic tinkling, resonance fair, few râles at left apex. Left lung seems to be slowly expanding. Liquids, 70 ounces; brandy, 10 ounces; toast, eggs, oysters.

December 6th. Breathing easier. Pulse fair, paradoxical. No abdominal distention. Sleeps six to seven hours. Blood: whites, 22,400. Chest: respiration at left apex fair; metallic tinkling and pericardial friction.

December 8th. Very dull over whole left back. Fair respiration. Few râles. Slight bronchial respiration with increase of fremitus and vocal resonance. Respiration deficient at right apex.

Condition varying from time to time; but gradual

improvement was noted up to December 20th, when the pericardium had closed. Only a superficial granulating wound on the 26th day after the operation. Much Cheyne-Stokes respiration when asleep. Twitching of legs and face at times (strychnia?). Movable flatness in left chest and the presence of fluid was suspected.

On December 30th the wound was entirely healed, and he was transferred to the medical side, to the care of Dr. F. C. Shattuck. For the next three weeks the temperature was irregular; and on January 23, 1896, the presence of pus in the left chest was demonstrated. Dr. Porter again operated, making an in-

CHART III.—Erysipelas.

cision in the mid-axillary line in the sixth interspace. About a quart of pus escaped. The cavity was washed out with diluted liq. sod. chlorinat. and boiled water, and rubber drainage-tubes introduced.

Six days later a resection of the fifth rib was found necessary to afford better drainage.

On February 7th, the eighth day after the resection, at the upper and outer edge of the incision a small area, raised, congested, indurated and slightly tender, appeared, which was pronounced by Dr. White to be erysipelas, and which gradually extended over the whole back of the neck and shoulder.

On February 13th the blood-count showed — reds, 3,500,000; whites, 19,500; hemoglobin, 40 per cent. The pus from the chest showed few pneumococci and no streptococci.

On February 19th, twelve days after the resection, the erysipelatous eruption had disappeared.

One week later an inflamed gland appeared in the left axilla.

The sputum was examined and no tubercle bacilli found.

On March 10th the axillary gland, which had suppurated, was opened and pus evacuated.

Gradual improvement took place in all respects until on March 25th, seven and one-half weeks after the resection, he was dressed and up for half an hour.

Constant and steady improvement; healing of the axillary wound. The empyema opening remained as a long, narrow sinus for many weeks, and finally closed seven months and three weeks after the operation for empyema.

A year after convalescence was established the patient was in excellent health and able to ride a bicycle a considerable distance without fatigue.

In considering the literature of purulent pericarditis, treated by incision and drainage, we find that the first recovery was a case of Rosenstein's in 1881. Since then 23 more cases have been reported; of this number nine have recovered, 15 died, and in one the result is unknown. The etiology of these cases is as follows:

	Rec.	Died.	Total.
Anterior Mediastinitis	1	1
Primary	1	2	3
Empyema	1	3	4
Trauma of chest wall	1	..	1
Stab in pericardium	1	..	1
Pneumonia	1	1	2
Osteo-myelitis	1	4	5
Pyemia (following abscess)	1	1	2
Tubercular	1	1
Unknown	1	3	4
	8	16	24

As will be seen by the table, osteo-myelitis appears as an important cause. One case followed a blow on the chest.

In one case pericarditis developed one month after a wound. Many of the cases were complicated with left empyema, and twice the pericarditis was discovered at operation while draining the empyema. Of the fatal cases, two died at operation; one lived two days; one (Delorme's case) lived eight weeks after the operation.

The organisms found in exudate were the staphylococcus aureus and streptococcus pyogenes, pneumococcus, and colon bacillus (in case of stab wound).

The amount of pus evacuated varied from ten ounces to two quarts. In one (Dickinson's case), it was brownish and thin with arterial blood); in two (Körte's and Eiselsberg's cases), foul and thick; in two (Newman's and Delorme's), thin. In the majority it was thick, creamy, without odor. In a number of cases, large fibrinous masses were found, the pericardium being covered with thick layers of lymph. At autopsy in one fatal case (Pepper's), the whole sac was full of a thick mass of fibrin as large as the fist; the drainage had been good, and the heart probably failed from pressure of these fibrinous clots. The shortest case of healing of the sinus after drainage was nineteen days, the longest two months.

Preliminary aspiration was done in all cases before opening the pericardium. In a number of cases paracentesis was done more than once, with and without injection of carbolic acid; and incision was finally resorted to owing to the rapidity of the reaccumulation.

The immediate relief to pulse and respiration was almost always striking.

With regard to the indications for the operation, we may affirm with confidence that the percentage of recovery after its performance warrants the statement that it is indicated in all cases of purulent pericarditis, and perhaps in serous pericarditis in cases where aspiration once or twice repeated is followed by reaccumulation of the fluid.

THE SURGICAL ANATOMY OF THE PERICARDIUM.

All authorities agree as to the great variations in the line of reflection of the pleura and pericardium.

Sick found that in the adult, out of 23 cases the

FIG. I.—Normal Contour of Pleura and Pericardium (Delorme and Mignon). pl, pleura; pe, pericardium; l, border of lung.

pleural reflection at the level of the fifth rib cartilage lay either at or within the left border of the sternum in 17; at the level of the sixth cartilage the pleural border had not gone beyond the sternal border in 10; at the level of the sternal articulation of the seventh cartilage it was in nine cases at the sternal border, or this cartilage was below its lower border. Twice it was less than one centimetre from the sternal border.

In 12 children Sick found at the level of the fifth rib cartilage the pleura was either within or just at the sternal border in 11. At the level of the sixth cartilage the pleura had not left the sternal border eight times.

It will thus be seen that, according to Sick's careful observations, even at the fifth space the reflection of the pleura will often be behind the sternal border. Brooks (quoted by Quain) in four out of seven quite healthy cases, found the left pleural reflection entirely behind the sternum, and in one at the sternal border.

According to Luschka (quoted by Quain) the pleura normally diverges from the median line at the upper border of the fifth costal cartilage, so that at the level of the fifth cartilage it is one-fifth centimetre, at the sixth, two centimetres, and at the seventh, 3.5 centimetres, external to the left border of the sternum.

Delorme and Mignon found in 32 adults that in the fourth interspace the left pleural border was within the border of the sternum in 17. At the level of the fifth cartilage it lay 15 times internal to the sternal border, and 17 times outside. In 12 cases at the fifth interspace the pleural border was at, or inside,

the sternal; and in the sixth space the pleural border was outside the sternum in 26 cases, and at or within it in eight.

Dr. Thomas Dwight, Professor of Anatomy at Harvard University, agrees in the main with Sick's observations, but states that there are many variations, and that frequently it is possible to reach the pericardium through the fifth intercostal space and frequently not. Owing to the fact that the sixth intercostal space is small and narrow, and that even here the pleura often reaches the sternal border, he concurs with the writer in advising resection of the fifth costal cartilage, and if necessary the excision of a piece of the sternum opposite this cartilage.

FIG. II.—Line of Pleura, abnormally to left of sternum (Delorme and Mignon). pl, pleura; pe, pericardium; l, border of lung; h, base of heart.

FIG. III.—Left Pleura, behind Sternum, reaching beyond middle line (Delorme and Mignon). pl, pleura; pe, pericardium; l, border of lung; h, base of heart.

The internal mammary artery, according to Quain, runs parallel to the sternum at a distance from it of one centimetre. Delorme and Mignon, in 30 cases, found it a distance from the sternum of from one-half to two centimetres, the distance averaging about the same in the first six interspaces.

In looking over the arrangement of the left pleura by Dwight, Delorme, Sick, Quain and Testut, all agree that there is a varied arrangement. Below the fourth

intercostal space in the majority, there is a slight interspace close to the border of the sternum which is free from pleura. In 22 operations on the cadaver by myself it was found that the removal of the fifth intercostal cartilage, and the removal of half an inch of the sternum opposite the sterno-costal joint, gave free access to the normal pericardium near its lowest level.

Three of the methods of operation which have been proposed and practised, namely, trephining the sternum (Riolan), approach through an intercostal space, and epigastric incision (Larrey), should all be discarded, as it will be evident from the above account of the anatomy that in all of them there is danger of wounding the pleura or diaphragm.

IDEAL OPERATION.

The following operation has been planned after careful consideration and experiment on the cadaver, in order as far as possible to meet the following indications:

(1) To avoid opening the pleural cavity. This may be made more easy by adhesions as a result of tapping or inflammation.

(2) To open the pericardium opposite the point where drainage will remain good after the sac has contracted.

(3) To secure permanent and free drainage.

The steps of the operation are:

(1) An incision from the middle of the sternum outward over the fifth costal cartilage to its junction with the rib.

The soft parts are cleaned from the cartilage with periosteum elevator, care being taken not to wound the pleura on the under surface. The cartilage is divided with bone forceps from the rib and the sternum. The internal mammary artery and vein are thus exposed, ligated in two places, and divided between. The triangularis sterni is separated from the sternum and pushed to the left.

A little careful dissection with the director in case fat is encountered, exposes the pericardium, which is normally much thicker than the pleura. An aspirating needle should now be introduced, if this has not been previously done, in order to corroborate the diagnosis. If confirmed, the knife should follow the needle. The incision in the pericardium is best made obliquely downward and outward, beginning close to the excised border of the sternum. The edges of the pericardium should be stitched to the soft parts.

Irrigation should always be employed, with the object of removing any masses of fibrin which may lie at the bottom of the cavity; and if there are many such masses, it should be continued until the fluid returns clear.¹ The fluid may be weak sublimate or carbolic solution, or salt solution, according to the preference of the operator. The fluid must be warm, and must have free exit.² With this exception no harm has resulted from irrigation, which has been practised in more than half the cases.

Drainage is best provided by two rubber tubes, one long and reaching to the bottom of the sac for the inflow, and a short tube just entering the sac for the outflow. As the discharge diminishes, one tube may be removed, and finally gauze drainage inserted. Gauze drainage has proved adequate from the first, but where

the fluid is thick or flocculent, tubes give the only adequate facilities for the subsequent daily irrigation.

The after-treatment must, of course, be directed to two ends: first, systemic treatment, consisting of forced feeding and free stimulation, to maintain the patient's strength; and second, the care of the wound and the maintenance of drainage. The wound should be irrigated daily and the patient, if his strength is sufficient to allow it, turned on his stomach to afford drainage.

The following cases have been reported of recovery from purulent pericarditis treated by incision and drainage:

Rosenstein, in 1881, had the first reported case of recovery. A boy of ten had been sick at home for two weeks, with pain in epigastrium, dyspnea and fever. On entrance there were signs of pericardial effusion. Aspirated twice in left fourth interspace, and a half-pint of pus evacuated. Finally, an incision was made over fourth space close to sternum: careful dissection to pericardium; pleural cavity adherent; large amount of pus evacuated; two rubber drainage-tubes inserted. Closure of sinus in nineteen days, and ultimate perfect recovery.

Gussenbauer. Boy of thirteen, osteo-myelitis of humerus, and pleurisy. Dulness of precordium not noted. Opened in fifth interspace in anterior axillary line, expecting to evacuate an empyema. Found effusion in pleura, and after resecting rib discovered enlarged pericardium. This was opened after aspiration, and pus evacuated. Rubber drainage, irrigation with thymol, recovery.

Davidson. Boy of six. Left empyema. Incision, evacuation of 10 ounces of pus. Ten days later high temperature, with increased cardiac dulness. Incision in fourth left interspace, one inch from sternum. Several ounces of creamy pus, drainage. Perfect recovery in five weeks.

Dickinson. Boy, aged ten. Pyemia from gluteal abscess. Left effusion into pleura and pyo-pericardium. Pleura aspirated nine times, and pericardium three times; finally, drainage in fifth interspace on right of sternum.

The operation was performed under ether with a narrow-bladed knife thrust along a trocar to right of sternum. Pus, blood and air escaped. Air probably sucked into pericardium by contraction of heart. Boy much better. No right pneumothorax; much discharge from the rubber tube; again in dyspnea; tube stopped up; exchanged for a larger one, and under good drainage immediate improvement. Air always bubbling through the tube with action of heart. Boy on his face three times a day to better drain the back of sac.

In three weeks two to three ounces of pus daily were draining from pericardium. The pus was still sweet. Tube in. In one week more the tube was removed and an oiled-silk wick inserted. In another week all healed. No mention of irrigation.

West's case, 1883. Boy, aged sixteen. Two months after an injury to chest there were signs and symptoms of effusion into pericardium.

Operation, September 14th. Paracentesis, fourth left intercostal space, just under nipple. Thirteen ounces of pus were obtained by aspiration, creamy and without flocculi. One-per-cent. carbolic-acid solution was injected, and allowed to flow out.

September 17th. Again worse. Paracentesis in fifth interspace, left nipple line. Needle passed into

¹ Cf. Delorme's case in which at the autopsy two handfuls of fibrin were found in the pericardium.

² Cf. Parker's case of death on the table from distention of the sac by irrigating fluid, which did not have free outflow.

enormous cavity, four and one-half inches without touching anything. Pus more flaky, and did not flow well.

Operation under chloroform. Narrow knife thrust along cannula as a guide. Two quarts of pus washed out with warm one-per-cent. carbolic solution. Rubber drainage-tube, one-half inch in diameter, inserted. Two ounces of 1-40 carbolic solution left in cavity. Very free discharge of sweet pus. Next day a soft catheter was inserted instead of tube. Irrigation with weak carbolic solution.

September 19th to 21st. Finger inserted, could just reach pericardial sac. Tube meanwhile washed with carbolic solution, 1-40.

September 25th. Tube removed, cleaned and replaced after washing cavity with carbolic. Cavity holds one ounce.

September 27th. Cavity closing. Very little discharge.

October 13th. Tube shortened. On the 14th it was removed; and on the 17th the incision was closed.

The operation was done September 14th, and the wound closed October 17th. Ultimate perfect recovery in one month.

Eiselsberg. October, 1893. The patient was stabbed with a knife over the heart. The wound healed a month afterwards. Fever, signs and symptoms of pericardial effusion.

January 20th. Trocar inserted in fourth interspace, and a quart of brownish, purulent fluid evacuated with great relief to symptoms.

February 2d. Thirteen days later. Evacuation in same manner of 900 grammes purulent fluid, with much less relief.

February 9th. Again, 1,000 grammes pus.

February 20th. Incision made over fourth left rib cartilage; and after resection of rib the healthy pleura, with lungs moving in it, could be seen. This was pushed aside and held off with iodoform gauze; then came out a thick, white membrane, which was aspirated and found to contain pus. An incision, four centimetres long, was made, evacuating two quarts of pus. This sac was then irrigated with warm salicylic-acid solution. The pericardium was sewed to the muscles and two drainage-tubes inserted. The pus contained large fibrin masses. The heart could be easily felt with the finger, beating powerfully.

During the first eight days daily dressing was necessary and irrigation was attended by escape of flocculi of fibrin. On the second day iodoform injections were made through drainage-tubes.

On the 17th day both tubes were removed; they had already been shortened. In four weeks more the wound entirely healed.

The colon bacillus was found in the fluid. It is a question whether it was on the original knife, got in later, or came through the blood. Eiselsberg believes in drainage if rapid reaccumulations occur after tapping, and speaks of the advantages of seeing where puncture goes, and thus avoiding injury to the heart.

Mr. H. Betham Robison. Male, age sixteen. Complained of sore throat, and on the following day developed diaphragmatic pleurisy on the right side. Six days later an unmistakable pericardial rub. The area of cardiac dulness increased much upwards and to the mid-axillary line laterally. About two weeks from date of pericardial involvement the aspirator

was introduced in sixth interspace just behind anterior axillary line. A small amount of pus obtained. Next day a piece of the sixth rib was resected, and left pleura opened. Lung fixed by recent adhesions. Pericardium incised, and pus washed out freely — over two quarts. No irrigation, owing to patient's feeble condition. Drainage-tube introduced, stitched to margin of wound. Tube removed on the sixty-first day after operation, and wound soon healed. At no time was there pus in the left pleura. Patient recovered fair strength. Can walk ten miles, but not equal to active exercise.

The following fatal cases have been collected:

Parker. Case of osteomyelitis of both tibiae, later development of pericardial effusion, fever. Aspiration in fourth left intercostal space. Eight ounces sweet, flocculent pus. Marked improvement. In four days return of effusion. A. C. E. mixture. Incision, two inches long, by left sternal border, centre opposite fourth interspace. One inch of fifth cartilage removed. On cutting through perichondrium, distended pericardium presented; this was sewed to chest wall and opened; much membranous pus and large flocculi of fibrin escaped. Irrigation with warm carbolic. Suddenly heart stopped beating, and patient died. Examination showed the sac distended with irrigation fluid, which had no proper escape.

Post-mortem. Lungs not collapsed. Pericardium much thickened, covered with large curds of pus, and layers of lymph.

Bronner. Girl of eleven. During an influenza epidemic, had first pneumonia of right base followed by another consolidation in left apex. In two weeks right empyema developed. A pint and a half of sweet pus was evacuated by incision. Pulse and respiration still remained high, though temperature was normal — pulse 145, respiration 45. Finally, signs of pericardial effusion appeared. Aspiration in fourth left intercostal space, one inch from sternum; pus appeared; incision carried down to pericardium. A quart of pus evacuated; rubber drainage inserted. Great relief after operation.

Temperature and respiration soon rose, in spite of free drainage and daily irrigations with boric acid. No harm resulted at all from these irrigations. Child gradually lost strength, and finally died, three weeks after operation. No autopsy allowed. Pericardial sac was felt to be full of granulations and not obliterated.

W. A. Edwards. In a child of six, symptoms of anterior mediastinitis, later of pericarditis. Aspiration of pericardium showed presence of pus. Drainage with rubber tube after incision in fifth interspace and evacuation of eight ounces of pus. Later, left empyema. Sixteen ounces of pus evacuated. Finally, resection of ribs was done and death followed. At the autopsy it was found that the pericardium was almost universally adherent to the heart, with here and there the intervention of fibrinous masses.

F. J. Newman. Man, age thirty-two, having been sick for three weeks. Symptoms were typhoidal until the week after admission to hospital, when signs of symptoms of purulent pericarditis developed. Aspiration in sixth interspace withdrew eight ounces of thin pus. Marked relief from profound collapse. In two days aspiration again in fourth right interspace, and 46 ounces of pus obtained. Three more times about the same amount was withdrawn at intervals of a few

days. Finally, a silver canula was thrust into the pericardial sac. Permanent drainage for two days, with irrigation with carbolic, 1-40. Then incision of sac with bistoury, and large drainage-tube inserted. Profuse discharge. Gradual and steady improvement to convalescence, when chills and bloody expectoration began, and in a few days death occurred. At autopsy there was found empyema on one side, plenisy on the other; the pericardium, much thickened (not ulcerated); some fibrin; sinus from pericardium was found advancing towards the second intercostal space; much inflammation of anterior mediastinum.

Savory. Boy with pyemia, after large abscess of the shoulder. Left empyema developed later. Twice aspirated. Finally an incision in the mammary line, fifth left interspace drained pus from localized empyema and revealed a much distended pericardium. This was opened and 24 ounces of creamy pus evacuated. Drainage and irrigation through catheter; profuse discharge. Child died at end of fifteen days. At autopsy lymph and adhesions were found walling off pleural cavity; parietal pericardium much thickened; good drainage of sac.

William Pepper. Young man of nineteen. Influenza; joint pains; temperature 104.2°; enlarged pericardium. After aspiration drainage by rubber tube in fifth left space; profuse discharge of pus. Lived two days. At autopsy a little pus was found in pericardium, but the whole sac was greatly distended with very large masses of fibrin. Regrets not making much larger incision.

Osler-Halsted. Purulent pericarditis after acute necrosis of bones of nose. Incision in fifth space. Drainage with gauze wick. Excellent drainage up to death in sixteen days.

Mr. Howard Marsh recorded a case of suppurative pericarditis. Male, age fourteen. Admitted to hospital in very exhausted condition. Incision made just below nipple, through an intercostal space. Pericardium bulged forward. Patient died on fourth day. No drainage-tube. Amount of fluid in sac not stated. No irrigation.

Körte. Child of seven. Osteo-myelitis of tibia, pyemia, with staphylococcus aureus. Large area of pericardial dulness; pulse 160; cyanosis. Aspiration in fifth left intercostal space; purulent fluid containing aureus. Resection of fifth rib for two inches from sternum. On opening pericardium a quart of offensive pus was evacuated. Pericardium was covered with an abundant coating of lymph. Irrigation had no bad effect on the heart, which improved after drainage. Abundant discharge for a number of days. Child died on twelfth day. At autopsy the pericardium contained considerable pus posteriorly, with purulent infiltration of myocardium and posterior papillary muscle. As there were also purulent foci in kidneys, an abscess of the heart wall was thought to have ruptured into the pericardium.

Davidson. Boy of six. Pyemia, after necrosis of third metatarsal bone; pleurisy; wandering pneumonia. Signs of enlarged pericardium, which was aspirated and opened in fifth interspace. Eight ounces of sweet pus were evacuated. A rubber tube, three and a half inches long, was inserted. No irrigation. Patient gradually failed and died on seventh day. At autopsy a small amount of sero-purulent fluid in each pleura; heart covered with lymph; drainage good.

Dr. O'Carroll, gives an account of a case of sup-

purative pericarditis secondary to pneumonia, which had been treated by free and constant drainage. The pericardial cavity contained less and less pus, but the patient died from asthenia two months afterward. The walls of the pericardial cavity were found to be adherent everywhere but in front, where there was about a drachm of pus. The puncture was made in the fourth space, a thumb's breadth internal to the line of the nipple.

Partzensky. Case of serous pericarditis of unknown etiology in a male twenty-three years of age. At the end of the third month of the disease paracentesis was performed and a litre of brownish serous fluid withdrawn. Eleven days later it was necessary to perform paracentesis again, and 100 grammes of pus were evacuated. On the following day an incision into the pericardium was made through the fourth intercostal space, much pus evacuated, and two drainage-tubes introduced. Lavage with a three-per-cent solution of salicylic acid. Death thirty hours after the operation. Autopsy: 100 grammes of pus in pericardium, fatty degeneration of myocardium, double adhesive pleurisy, and hypertrophy of the right side of the heart.

Klefberg. A sailor, aged nineteen years, had an enormous purulent pericardial effusion following influenza. Puncture and aspiration of 150 grammes of pus. Great cyanosis. Pulse could not be counted. Incision in fourth intercostal space under local anesthesia. More than one litre of pus evacuated. Death on the sixth day. Autopsy: pericardium empty, but pus in right ankle-joint and right sterno-clavicular joint.

Sievers. A woman, twenty-two years old, had purulent pericarditis following a right-sided empyema. Paracentesis showed a sero-purulent fluid; and two days later an incision in the third intercostal space opened the pleura and then the pericardium. Sero-purulent fluid, drainage. Improvement in pulse and general condition. Four days later empyema developed on the left, and pleurotomy was performed. Death occurred six days after opening the pericardium, and a not inconsiderable amount of purulent fluid was found in the pericardial sac. Double purulent pleurisy was also found.

Delorme and Mignon. Two cases.

The first was a male, nineteen years old. A case of empyema following influenza, operated on by Delorme, was followed by pericarditis three days after the operation. The pericardium was opened in the fourth intercostal space by the same operator after a superficial examination, which was all that the moribund condition of the patient would allow. Only a few drops of fluid escaped, and the patient died in a few minutes. The autopsy showed the heart adherent to the whole anterior surface of the pericardium, except at its lower part; 500 grammes of sero-purulent fluid were collected in the lower and back part of the pericardium, together with a double handful of flakes of fibrin. If the incision had been carried further downward and to the left, this fluid would have been reached. Paracentesis, as ordinarily performed would have wounded the adherent heart.

The second case was a male, twenty-two years old. Tubercular pericarditis and left pleurisy. Incision in the fourth intercostal space. Pleura was opened, and 250 grammes of serous fluid escaped. An incision being made through what was supposed to be

the pericardium, and no fluid escaping, the latter was thought to be adherent to the heart, and operation was suspended. Death, eight weeks later, of tubercular meningitis. Autopsy showed heart adherent to anterior surface of pericardium, and a large amount of fluid distending the sac below and behind.

The following case is added to the list, although it is one of serous and not purulent pericarditis, as showing that incision may be of benefit where puncture has failed to permanently relieve.

Rullier. Serous pericarditis. Tapped four times and then injected with iodine, but the effusion returned. The pericardium was incised in the fourth left intercostal space. Recovery was delayed by left bronchopneumonia, but was finally complete.

AN EXHIBITION "FOR THE HYGIENE OF CHILDHOOD."—A national German exhibition "For the Hygiene of Childhood at Home and at School" is to be held in Breslau at the end of May.

ASEPSIS AND GALLANTRY.—The Hungarian Government permits women to study medicine if they so desire, but one of the professors at the University of Budapest has recently proclaimed that he has something to say in the matter. Of the five women now studying medicine there, one has a remarkably fine head of hair, which the professor of surgery says must come off before she can be permitted to attend his clinics. The reason he gives for his prohibition is that "wool carries infection."—*Medical Review*.

THE MORTALITY RATE IN NEW YORK CITY.—The effect of the sudden change in the weather from balmy spring to the blasts of winter which occurred in the early part of last week is reflected in the increased mortality of the week, the number of deaths reported being 815, against 749 in the week ending April 24th. Much illness and a large number of deaths have been directly attributable to the exposure of the people to the northerly gale, with its attendant clouds of dust, during the long hours of the Grant Monument celebration. Four deaths from small-pox were reported during the week.

THE BOSTON Medical and Surgical Journal.

THE TREATMENT OF PNEUMONIA AND OF INFLUENZA BY LARGE DOSES OF DIGITALIS OR DIGITALIN.

PETRESCO, of Budapest, is known to have been the most earnest advocate of the treatment of pneumonia by digitalis. His contributions have been numerous since 1880, when he first set forth the claims of this method of treatment. As these views have already been fully stated in this JOURNAL, we shall very briefly sum up his conclusions preparatory to indicating the results of the recent clinical experimentation of Gingeot and Deguy.

It will be remembered that the doses which Petresco recommends are enormous as contrasted with what has ordinarily been regarded as the safe dose of digitalis, Petresco stating that he does not hesitate in single doses to give as much as three drachms (180 grains) of digitalis leaves in twenty-four hours. He prefers the infusion made with five parts of digitalis leaves in two hundred of water, and then adding forty parts of syrup of orange-peel, the dose then being a tablespoonful every half-hour. He affirms that in general this dose is well borne, and that he has never met with a single case of poisoning. He says that he has had the best results in genuine fibrinous pneumonia, though he has obtained satisfactory results in broncho-pneumonia and in pleurisy. He claims in the most positive manner to have cut short cases of croupous pneumonia, so that within twenty-four to forty-eight hours he has succeeded in obtaining sudden and almost absolute reduction of the temperature to the normal with strengthening of the pulse and general improvement in the patient's condition. The most evident effect is the marked slowing of the pulse with increased tension; at the same time disappearance of all the local symptoms of pneumonia can be noted. He enforces the value of this method of treatment by statistics, the mortality of cases so treated with large doses of digitalis being much less than that observable when any other method is employed.

It must be admitted that the medical profession has been slow to adopt this new mode of treatment, and few have had such brilliant results as Petresco claims. Lowenthal's trials in the Vienna hospital were unsatisfactory, the patients (twelve in number) indeed recovering, but with depression and exhaustion increased rather than diminished, and a somewhat lengthened convalescence. Renier's experience in twenty-five cases is very similar to that of Lowenthal. In one of Renier's cases alarming symptoms of collapse lasting for six days came on. He attributed this collapse, which was characterized by cyanosis, sunken face, vomiting, small and intermittent pulse, cold sweat, hiccough and stupor — to the digitalis.

Gingeot and Deguy have published their trials with digitalis in pneumonia and *la grippe* in the *Revue de Médecine* for March, 1897.¹ They do not give the digitalis in the form of infusion, but they use the crystallized digitalin, in a one-per-cent. solution. Fifty drops of this solution contain one milligramme of the alkaloid. To obtain certain and rapid effects, they administer, early in the disease, one massive dose of a milligramme, and give no more medicine of any kind for five or six days. In proceeding thus, they have never observed any untoward accidents. At other times they give smaller doses of digitalin, and repeat them till the desired effect is obtained: thus, instead of the one full dose of fifty drops, they give twenty drops per day for two days, and then stop. But whatever may be the mode of administration of the medicament, it is not desirable to exceed the quantity of sixty drops of the centesimal solution in seven days.

They affirm that the digitalin is particularly efficacious when the pneumonia of influenza is not accompanied with digestive troubles.

In a dozen cases of pneumonia treated by this method, these authors have not had a single case of death, and they have obtained recovery in two desperate cases of double pneumonia. Under the digitalin treatment, the patient generally feels decidedly better the second day after the full dose has been administered; the delirium ceases, the albumin diminishes to soon disappear altogether; the temperature falls and the pulse becomes less frequent but more energetic; the diuresis augments; the congestions are dissipated, and the pneumonic exudate is absorbed more rapidly than in cases when the digitalin is not employed. In short, the digitalin accelerates the normal evolution of the malady.

What has been said of frank pneumonia applies also, according to these writers, to the broncho-pulmonic determinations of *la grippe*, and the same treatment is also useful in grave or complicated gastro-intestinal forms, especially when the pulse is feeble, small and rapid.

In cases of *la grippe* simulating tuberculosis the digitalin has given better results than any other treatment (quinine, cold baths, antipyrin, etc.). Another fact has been noted by MM. Gingeot and Deguy —

the employment of digitalin may render service from the point of view of differential diagnosis. They affirm that they have never been able by means of digitalin to obtain an antithermic effect in acute tuberculosis or typhoid fever. On the other hand, in cases of the grip simulating military tuberculosis or typhoid fever, the administration of digitalin has always brought on rapid defervescence, while ameliorating the other symptoms.

One of the observations related by Gingeot and Deguy well illustrates the help which this treatment gives towards the differential diagnosis of certain doubtful affections. A patient presented himself for treatment with intense dyspnea, a decidedly pneumonic aspect and a focus of subcrepitant râles in the right infra-axillary space. The diagnosis of pneumonia in the first stage was made, and 30 drops of the solution of digitalin administered. The next day the condition of the patient was worse, and 20 drops more of the solution were given, but without any improvement in the pulse or general state. The day following, the patient succumbed in coma. The autopsy showed that this was not a case of pneumonia, but of typhoid fever with all the characteristic lesions of Peyer's patches.

The conclusion drawn from the study of this and like facts is that when the administration of digitalin to a person supposed to be affected with pneumonia or influenza does not slow the pulse and ameliorate the condition, there is reason to believe that an error in diagnosis has been committed.

TWENTY-EIGHTH REGISTRATION REPORT OF MICHIGAN, FOR THE YEAR 1894.

In one respect the course taken by the State of Michigan in the treatment of the vital statistics of the State is highly commendable, and that is in its appointment of a medical man, previously well-trained in statistical methods to take the entire charge of this important department. In another direction, however, the action of the State is seriously defective, since it has never succeeded in securing a complete registration of the births and deaths, the returns, in the words of this report, being deficient to "such a degree that they would require to be increased by at least sixty per cent., to correctly represent the actual numbers of births and deaths that occurred."

Legislation is now proposed, and endorsed heartily by the medical profession of Michigan to remedy this defect. With these deficiencies in view, the compiler of this report is to be congratulated upon the fact that this document for the year 1894 is the best of any of the State Registration Reports of that year, notwithstanding the difficulties due to the deficiencies which have been mentioned.

The report begins with a full statement of the population by sex, nativity and ages; and in this portion a full table is presented giving the vital statistics of other States and Countries. In the section which

¹ See also *Semaine Médicale*, March 15, 1897.

relates to births it appears that the actual births in 1894 were equivalent to a birth-rate of 19.4 per 1,000 of the population; but, estimating the deficiency of returns, the probable birth-rate was 31.8 per 1,000.

A new feature in this report, not to be found in any other American reports of recent date, is the subject of "Fecundity of Marriage." The compiler, Dr. Wilbur, makes the following distinction in the terms fecundity and fertility, defining the former as the fruitfulness of marriage, and the latter, as the fruitfulness of women of child-bearing age. A table is presented in which the author, after correcting the figures for omissions, estimates the number of children born to each marriage to be 2.9 for the native population in the period 1890-94, and 6.6 for the foreign population in the same time.

The registration of marriages is believed to have been fairly complete, and the marriage-rate was 16.3 per 1,000 in 1894 (persons married).

The death-rate estimated from the actual returns was 9.3 per 1,000; but, allowing for deficiencies, the true death-rate is believed to have been 15.0 per 1,000 of the living population. The compiler states that the deficiency in the returns is largely due to the fact "that births and deaths are not registered immediately upon their occurrence, but are supposed to be collected at the close of a registration year, or some time afterward."

In that portion of the report which treats of the causes of death, Dr. Wilbur makes a bold departure from the old and time-worn conventionalities of classification which have served their time and generation since the days of Dr. Farr. Under the light of modern discoveries as to the intimate causes of disease, the old classification into five groups (zymotic, constitutional, local, developmental and violent deaths) begins to appear strangely incongruous. In the Michigan report, therefore, a provisional classification is adopted, which, as the author says, "was designed merely for use until a satisfactory nomenclature shall be authoritatively introduced and adopted by American registrars."

In this classification all the dangerous communicable diseases, including consumption and other tubercular diseases are grouped together. It appears from the table that this class of diseases has diminished from 363 in each 1,000 of the total mortality in the five-year period 1870-74, to 282 in each 1,000 in the period 1890-94, and still further to 258 in the year 1894. Consumption also diminished in the same time from 142 to 121 in each 1,000 deaths from all specified causes. The same may be said of typhoid and scarlet fever, measles, small-pox and whooping-cough. On the other hand, cancer, heart diseases, kidney and lung diseases have increased; wherein Michigan resembles in its vital statistics the condition of other States and countries having registration.

Considerable space is given to the subject of "Diphtheria and Croup," the compiler preferring the method of considering these separately instead of

combining them as is usually done. It is shown that the mortality from diphtheria in 1881 in Michigan exceeded even that from consumption and was relatively greater than that of the Eastern States from the same cause.

MEDICAL NOTES.

THE FRENCH CONGRESS OF ALIENISTS AND NEUROLOGISTS will be held in August at Toulouse. Questions to be discussed: "Diagnosis of General Paralysis," "Infantile Hysteria," "Medical Service in Insane Asylums."

BOSTON.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, May 5, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 95, scarlet fever 84, measles 134, typhoid fever 10.

Correspondence.

WILLIAM G. WHEELER.

EVERETT, MASS., April 30, 1897.

MR. EDITOR: — Dr. William Goodnough Wheeler, one of Chelsea's best known and most beloved physicians was called to the higher life on Saturday, April 17, 1897, after a patient endurance of severe and prolonged illness.

In Chelsea for half a century he had given strict and devoted attention to his much-loved profession. His natural ability, developed by careful training, intelligent grasp of difficult problems, and his abundant supply of good common-sense were quickly recognized by a discerning public and brought to him many calls to positions of honor and laborious service, not only in his own city, but beyond.

Dr. Wheeler was ever abreast of the times, and kept in touch with the latest developments of medical science. He not only held a membership in the different medical societies of Massachusetts but was held in high esteem by his brethren.

Dr. Wheeler, while following the general practice of medicine, was also prominent and successful as a surgeon, and that when surgery had no such safeguards as are possessed to-day.

Dr. Wheeler was a scholar of refined taste, a great student and lover of Shakespeare, and a discriminating reader of the best books.

In person he was of commanding figure, regular and attractive features, manly and engaging presence. His manners were those of a refined and cultured gentleman; he was ever cheerful and kindly, but never frivolous.

He despised mean things and loved those things that were noble and pure. In his home, as by the bedside of his patients, he was ever agreeable; his hopeful spirit was so contagious as to make his presence a benediction, and his smile better than medicine.

In religion Dr. Wheeler was an Episcopalian, being a member of St. Luke's Church from the time of its organization in 1847 until he was called home. He was never ostentatious in his religious life, but was profoundly moved by the truths of God's Word to a practical piety and a benevolent sympathy. Scorning all cant and mere pretence in sacred things, he believed God and loved his fellowmen.

Yours very truly,

A. A. JACKSON, M.D.

METEOROLOGICAL RECORD

For the week ending April 24th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 3,372; under five years of age 1,089; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping cough, erysipelas, diarrheal diseases and fever) 367, acute lung diseases 539, consumption 421, diphtheria and croup 127, diarrheal diseases 59, scarlet fever 42, cerebro-spinal meningitis 36, whooping-cough 32, typhoid fever 30, measles 23, erysipelas 12, malarial fever 3, small-pox 3.

From cerebro-spinal meningitis Boston 11, New York 7, Washington 5, Hyde Park 2, Baltimore, Cleveland, Worcester, Cambridge, Lynn, Somerville, Newton and Taunton 1 each. From whooping-cough New York 10, Philadelphia 7, Chicago 6, Brooklyn 3, Boston and Cleveland 2 each, Washington, Lowell, Cambridge and Everett 1 each. From typhoid fever Philadelphia 11, New York 4, Chicago, St. Louis, Cincinnati and Cleveland 2 each, Brooklyn, Baltimore, Boston, Lowell, Somerville, Salem and Haverhill 1 each. From measles New York 6, Chicago 5,

Brooklyn 4, Philadelphia 3, Boston, Cincinnati, Providence, Lowell and Taunton 1 each. From erysipelas New York 6, Philadelphia 3, St. Louis, Baltimore and Providence 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,992,524, for the week ending April 17th, the death-rate was 17.9. Deaths reported 3,754; acute diseases of the respiratory organs (London) 273, measles 105, whooping-cough 100, diphtheria 51, scarlet fever 33, diarrhoea 30, fever 16.

The death-rates ranged from 9.5 in Croydon to 28.1 in Salford; Birmingham 18.5, Bradford 13.8, Cardiff 16.9, Gateshead 19.1, Hull 16.5, Leeds 22.3, Leicester 17.4, Liverpool 22.6, London 16.6, Manchester 23.3, Newcastle-on-Tyne 15.7, Nottingham 11.9, Portsmouth 16.8, Sheffield 15.7, Sunderland 17.2, West Ham 13.3.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 24, 1897, TO APRIL 30, 1897.

Leave of absence for four months and fifteen days, to take effect on or about May 27, 1897, with permission to go beyond sea, is granted CAPTAIN FRANK R. KEEFER, assistant surgeon, U. S. Army, Washington Barracks, D. C.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 1, 1897.

A. G. CABELL, surgeon, ordered to the "Monongahela," May 15th.

D. H. MORGAN, surgeon, has been detached from the Naval Academy and ordered to the "Monongahela," May 15th.

R. G. BRODRICK, assistant surgeon, ordered to examination for promotion, May 3d.

F. C. COOK, assistant surgeon, detached from the "Vermont," May 8th, and ordered to the "Wilmington," May 10th.

SOCIETY NOTICES.

NEW HAMPSHIRE MEDICAL SOCIETY.—The one hundred and sixth anniversary meeting of this Society will be held at Concord, Monday and Tuesday, May 24 and 25, 1897.

The annual meeting of the Alumni of Dartmouth Medical College will be held at the Eagle Hotel, May 24th, at 6 o'clock P. M., and will be followed by a banquet.

ABEL P. RICHARDSON, M.D., *President*.
GRANVILLE P. CONN, M.D., *Secretary*.

NORFOLK DISTRICT MEDICAL SOCIETY.—The annual meeting and dinner of this Society will be held at the Old Dorchester Club House, Tuesday, May 11, 1897, at 12 M.

The Annual Address will be given by J. A. Tanner, M.D.

The Board of Censors will meet for the examination of candidates on Thursday, May 13th, at 2 P. M., at the office of the Supervisor, 1 Elm Hill Avenue, Roxbury. The written examination will begin at 2 P. M., the oral at 4 P. M.

J. C. D. PIGEON, M.D., *Secretary*, 130 Warren Street.

BOOKS AND PAMPHLETS RECEIVED.

GALL-BLADDER INFECTION IN TYPHOID FEVER.

WITH THE REPORT OF A CASE IN WHICH TAPPING THE GALL-BLADDER RESULTED IN CURE.¹

BY A. LAWRENCE MASON, M.D., BOSTON.

INFLAMMATION of the gall-bladder, sometimes resulting in ulcerative perforation or in rupture from distention with consecutive peritonitis, has long been noted as an occasional complication in fatal cases of typhoid fever. The clinical evidences of this condition have usually been masked by the general abdominal symptoms of the disease so that the localization of pain or tumor in the region of the gall-bladder and the recognition of this appendage as the immediate source of danger have not been practicable. Therefore, most of the recorded cases, some forty in number, have been post-mortem discoveries; or, if the state in question has oftener been surmised at the bedside, it has seldom been the subject of accurate observation or of surgical interference. There are a few instances, however, in which this localized inflammation presents such striking symptoms that its seat and nature can be determined and thus impending danger may be averted. Such an instance affords the basis for this paper, in which I will relate the history of a case of typhoidal cholecystitis and then refer to the literature bearing upon this subject and the deductions to be drawn therefrom.

A woman, aged thirty, entered the Boston City Hospital in the third week of typhoid fever, with dry, brown tongue, palpable spleen, rose-spots and distended abdomen. Anorexia, vomiting and constipation had been prominent symptoms. Widal's serum test was positive, but not immediate; clumping of bacilli and loss of motility in fifteen minutes. Leucocytes, 9,600. Typhoid deafness. Toward the end of the third week she complained of increasing abdominal pain that became localized in the right hypochondrium, where a tumor four inches in diameter developed, extending from the costal border toward the umbilicus. This tumor caused a visible swelling, was very tender, absolutely dull on percussion, and descended on full inspiration. At the time of admission, a week earlier, the liver dulness had been normal, and there was no special pain in this region. Now the patient's condition showed partial collapse, and as suppurative distention of the gall-bladder was thought to be present, my surgical colleague, Dr. George W. Gay, saw her in reference to an early laparotomy because rupture of the gall-bladder seemed imminent. Her state was regarded as unfavorable to the success of a capital operation, therefore I at once tapped the gall-bladder at a point one inch below the costal margin and four and a half inches from the umbilicus. Three and a half ounces of sero-purulent fluid were withdrawn, pale in color, looking more like urine than bile. The aspirating needle moved up and down with the action of the diaphragm. No gall-stones could be felt with the point of the needle. After its withdrawal a pad and swathe were applied to prevent the escape of septic fluid into the peritoneal cavity. The relief to pain was immediate. The next day all urgent symptoms had disappeared, and they did not return. The pulse

fell from 140 to 120, and defervescence followed in five days. The gall-bladder gradually retracted; convalescence ensued; and when the patient returned for observation a month later, nothing abnormal was found in this region. (A photograph and chart were presented, together with a specimen of the fluid withdrawn. The chart is herewith produced.)

The following report was made by Dr. R. M. Pearce, assistant to Dr. Councilman in the Pathological Laboratory of the City Hospital:

The fluid is of a pale yellowish color, watery consistency and fecal odor, with considerable fine, yellowish sediment, in which fine reddish-yellow granules could be seen. Specific gravity, 1.016; albumin, one per cent.

Fresh examination, microscopically, shows much bile pigment, numerous cholesterol crystals, pus cells and epithelial cells, most of the latter being granular and some fatty.

Sediment stained with Löffler's methylene blue shows pus cells, epithelial cells, and numerous short, thick bacilli with rounded ends, occurring singly and in pairs, and usually in the pus cells, arranged in clumps around the nucleus.

Cultures show round, flat colonies with elevated centres, of pale white color, almost transparent; microscopically, short, thick bacilli with rounded ends and very motile. No other bacilli.

Cultures from dilutions, planted on potato, produced invisible growth; in litmus milk no reddening or coagulation; in sugar gelatin no gas production. Flagella stained.

With serum from a known typhoid case characteristic clumps, with loss of motility, were produced. The same reaction was produced with the patient's own serum.

Diagnosis: Typhoid bacillus.

December 7th, 3 P. M. A guinea-pig was inoculated subcutaneously with one cubic centimetre, and one cubic centimetre intra-peritoneally of forty-eight-hour bouillon culture.

¹ Read before the Association of American Physicians, May 4, 1897.

A large, subcutaneous abdominal abscess developed, which burst and discharged.

December 20th, 1 P. M. Pig killed. Autopsy showed general edema of abdominal tissues; marked enlargement of inguinal and axillary glands; large slough, two centimetres in diameter, at seat of inoculation; fluid in abdominal and pleural cavities; marked enlargement of mesenteric and retro-peritoneal glands; spleen enlarged, reddened, follicles distinct; Peyer's patches enlarged; intestinal tract otherwise normal. No changes apparent in other organs.

Dr. S. W. Ellsworth, house physician, used pure cultures of the bacilli found in this fluid in further clinical tests for Widal's reaction, as follows:

With the serum from eight cases of typhoid fever the characteristic clumping and loss of motility were quickly obtained.

With serum from one case each of malaria, pneumonia, phthisis and rheumatic fever the results were negative, as they also were in further testings of the serum from these cases with a pure culture of typhoid bacilli from a spleen.

The records of the Boston City Hospital, so far as I am aware, contain but three other cases of this complication in typhoid fever, and these occurred in the same family, as reported by Dr. C. Ellery Stedman in the third Series of City Hospital Reports, 1882.¹

They are, briefly, as follows:

CASE I. A girl, aged thirteen, died on the 24th day with symptoms of peritonitis. At the autopsy the usual lesions of typhoid fever were found, and in addition adhesive inflammation in the region of the gall-bladder, which was glued to the colon at the junction of the ascending and transverse portions. The fundus of the gall-bladder was ulcerated and ruptured, and there was a pint and a half of yellowish serum in the abdominal cavity. No gall-stones.

CASE II. A girl, aged six, sister of the above, died of typhoid fever on the 28th day, and the post-mortem examination showed extensive peritonitis, with a pint of sero-purulent fluid in the abdominal cavity. There were three perforations of the gall-bladder and extensive ulceration of its inner surface.

CASE III. Male, aged sixteen, brother of the above, developed a tender, rounded tumor in the region of his gall-bladder in the second week of typhoid. This gradually subsided, and the patient made a good recovery.

LITERATURE.

In examining the history of this subject during the past sixty years we find some forty cases recorded in which destructive inflammation of the gall bladder during typhoid fever has attracted attention as a matter of special interest, usually after death. Few of the earlier, and almost none of the later, works on medicine give it more than a passing mention, and the unusual localization of the lesion so *bizarre*, as it was termed by a French writer, has until recently found no satisfactory pathological explanation.

Louis in his work on "Typhoid Fever"² states that "changes in the bile and gall-bladder are much more frequent in the course of the typhoid affection than in that of other acute diseases." He cites three fatal cases in which cholecystitis, unrecognized during life, had supervened. In two the gall-bladder was filled with a "transparent, aqueous, diaphanous or urinous liquid" and in one case the cystic duct was obliterated.

Similar cases are mentioned by Andral, Grissolle, and

by other writers in the French journals since 1835, to which reference is made at the end of this article.

In the German writings before 1890 are several communications based upon the discovery of post-mortem typhoidal lesions of the gall-bladder, but I will mention only the observations of Rokitsansky and Frerichs and Hölischer's autopsy records.

Rokitsansky³ speaks of fibrinous exudations of a "diphtheritic" character as occurring within the gall-bladder and ducts in typhoid fever, cholera and pyemia, their existence being indicated by no symptoms during life and only determined by post-mortem examinations. This is not an adequate description of the process under discussion.

Frerichs⁴ on the other hand, found the gall-bladder filled with a turbid, ash-colored, albuminous fluid, of neutral or feebly alkaline reaction, in three cases of typhoid fever and one of typhus. In two cases bile-pigment and biliary acids were entirely absent; in the other two small quantities of these substances and some leucine were found. The lining membrane of the gall-bladder and ducts was softened and pale. There were no gall-stones, and no jaundice or other hepatic affection was present.

Frerichs also gives the following description of a case that recovered:

A female, aged twenty-six, on the 13th day of a typhoid fever had attacks of vomiting, and two days later a very painful, pear-shaped tumor was found in the right hypochondrium in immediate connection with the liver above. It gave a muffled, tympanitic percussion tone. There were no signs of biliary obstruction. Leeches and cataplasms were applied. The vomiting ceased altogether; nausea continued for many days. Pain and tension diminished, and the boundaries of the tumor contracted until, in the fourth week, convalescence ensued, although the gall-bladder could be felt for a long time.

There is a noticeable similarity between this history and that of my case, except that the withdrawal of the fluid enabled us to determine both its source and cause by methods that were not formerly available.

In Hölischer's⁵ 2,000 typhoid autopsies marked hepatic degeneration was found in more than ten per cent. of the cases. In 22 only jaundice was present, and in but five was purulent inflammation of the gall-bladder discovered. In a single case there was perforation with circumscribed peritonitis.

Courvoisier,⁶ in his elaborate work on "The Pathology and Surgery of the Biliary Passages," records 10 fatal cases of typhoid cholecystitis, two with gall-stones and phlegmonous infiltration of the gall-bladder walls, and seven with sero-purulent exudate, occasional ulcers and necrotic areas. In four cases of perforation no gall-stones were present.

Among English authorities Budd⁷ relates a case which came under his care in 1849:

CASE. A female, aged eighteen, entered King's College Hospital in the second week of typhoid fever. During the third week she lay delirious, on her back, with legs drawn up, and gave signs of pain when the region of the liver was pressed upon. "On the 19th day," says Dr. Budd, "when I made pressure on the belly to the right of the epigastrium she uttered a loud shriek. I now discovered a fulness in that part of the belly, and inferred that there was inflammation of the gall-bladder or that an abscess existed in the liver." Chills and vomiting followed, but the patient

lived two weeks longer. There was no jaundice. Autopsy showed a distended gall-bladder, an inch and a half below the liver-margin, with recent peritoneal adhesions to the surrounding parts. It contained considerable puriform fluid and fourteen gall-stones, one of which completely blocked the cystic duct. They consisted of a cholesterine with nuclei of inspissated bile. The liver itself presented no unhealthy appearance. Extensive ulceration of Peyer's patches.

Budd remarks that "suppurative inflammation of the gall-bladder seems especially liable to occur when by any cause the cystic duct is permanently closed."

He regards the purulent and ulcerative inflammations of the gall-bladder in typhoid as similar to the appearances observed in the violent remittent fever that prevailed with great fatality among the British troops on the Island of Walcheren in 1809, in the fever of Sierra Leone and in yellow fever.⁸

Murchison, Harley and Hale White make special reference to the cholangitis and cholecystitis that may attend typhoid fever.

Murchison⁹ states that in this disease "fatal peritonitis may result from ulcerations of the gall-bladder proceeding to perforation." He cites the case of a youth who on the 15th day was seized with symptoms of peritonitis and died within twenty-six hours. The cause of death was perforating ulcer of the gall-bladder which had allowed bile to flow into the peritoneum.

This author further says: "The lining membrane of the gall-bladder is very liable to become inflamed in enteric fever without producing any marked symptoms during life. This inflammation is sometimes catarrhal, with pus formation; at other times, according to Rokitsky, it is diphtheritic. Thirdly, it may take the form of ulceration, as in cases recorded by Audral, Jenner and Trousseau, and the process may end in perforation and fatal peritonitis. In a large proportion of cases when the disease has lasted three or four weeks the bile is thin, watery, almost colorless, of low specific gravity, 1.010 to 1.016 instead of 1.026 to 1.030."

Murchison mentions several other cases by different authors as well as in his own practice.

Harley,¹⁰ after commenting upon the usual hepatic degeneration in typhoid, says that he constantly found the bile thin, watery and of low specific gravity, giving slowly and faintly the characteristic reactions when tested with the mineral acids or by Pettenkoffer's test. It was sometimes excessively acid, and in one case, examined twelve hours after death, had a strong smell of sulphuretted hydrogen. Harley's view of these biliary changes is that the hepatic secretion becomes vitiated either by prolonged vascular congestion or through "the effect of some morbid agent carried by the portal vein from the intestinal surface into the liver," which may, at an early period in the disease, cause torpidity of that organ and more or less complete cessation of its functions.

Although our own authors have not made such extensive reference to the biliary complications of typhoid fever as the writers to whom I have referred, they mention the danger to life that may arise from suppuration within the gall-bladder; and beside the cases of Dr. Stedman previously quoted, I have found a few others.

Dr. Daniel Ayres¹¹ in 1846, described "A Case of Perforating Ulcer of the Gall-Bladder complicating Continued Fever."

CASE. A young hospital interne, during convalescence from typhoid fever, was taken with acute pain in the right hypochondrium and died of peritonitis. At the autopsy a perforating ulcer at the fundus of the gall-bladder was found and the abdominal cavity contained ten ounces of biliary fluid, serous in character. The ducts were patent and there were no gall-stones.

Ayres mentions the cases of Budd and Louis, which were then recent, and, after alluding to their analogy in this respect with yellow fever and other diseases of tropical climates in which inflammation and ulceration of the gall-bladder may occur as a sequence to biliary derangements, he concludes that "perforation generally supervenes upon a previously diseased state of the gall-bladder and very rarely appears in the course of acute diseases without such a cause."

An interesting case is reported by Dr. William Pepper,¹² and is quoted by Frerichs as bearing upon this subject:

CASE. A man, twenty-six years old, had a prolonged bilious fever, and came under the care of Dr. Pepper six months later with severe pain and a tumor in the right hypochondrium which gradually extended as far as the crest of the ilium. It was tapped, and a few ounces of muco-purulent fluid were withdrawn. After death the gall-bladder was found enormously distended by two quarts of semi-purulent fluid. The walls were ulcerated, and the cystic duct was completely closed by exudate. No gall-stones were present. There were two small abscesses in the right lobe of the liver.

The most comprehensive study that had then appeared (in 1876) is contained in the Paris Thesis on "Cholecystitis in Typhoid Fever," by Hagenmüller.¹³ Eighteen cases from French and German reports are collected. In four cases there was slow recovery; in the others, death from peritonitis, the affection of the gall-bladder having been unrecognized during life. Hagenmüller's conclusions were that typhoidal cholecystitis, apparently so rare, will be more frequently observed when attention is awakened to the subject; that it results from the propagation of the intestinal inflammation to the gall-bladder, owing to low systemic conditions; that the diagnosis must be based upon the localization of pain in the right hypochondrium or in some cases upon intumescence of the gall-bladder; and that fatal peritonitis may result from perforation or from simple extension of the inflammation to the peritoneum by contiguity. In but two cases were gall-stones found, and rarely did the inflammation involve the liver substance.

During the past decade only has it been possible to apply the methods of bacteriological research to these obscure lesions and to trace the gall-bladder infection directly to the typhoid bacillus.

In 1890 Gilbert and Girode¹⁴ reported the first case of suppurative cholecystitis caused by the invasion of typhoid bacilli, as demonstrated microscopically and by cultures. In 1893 the same authors presented a further communication relating to the same subject.¹⁵

CASE. A woman, aged forty-five, during a moderately severe typhoid fever had symptoms referable to the gall-bladder, pains and a swelling in that region. With convalescence the swelling diminished, but after a considerable interval the symptoms returned, and on re-admission to the hospital, five months after the termination of the typhoid attack, cholecystotomy was performed. The gall-bladder contained pus which

gave a pure culture of typhoid bacilli, and there was also a small calculus.

E. Dupré in a comprehensive thesis on "The Biliary Infections" ¹⁶ gives two cases (Observations VII and IX) in which he had made pure cultures of the typhoid bacillus from the gall-bladder. The first was that of a man, forty-six years old, who died on the 16th day of his fever. Although the gall-bladder presented no apparent pathological changes, pure cultures of Eberth's bacillus were obtained. The second observation relates to a woman, forty-five years old, who died from an operation for gall-stones, performed six months after recovery from typhoid fever. The discovery of typhoid bacilli in both gall-bladders led the author to think that this infection was more common than was supposed.

In 1892 Guarnieri ¹⁷ found an infection of the biliary passages, liver and spleen by the typhoid bacillus in a case that presented no intestinal lesions.

Chiari's ¹⁸ report of a case of destructive cholecystitis, in which the pathogenic organisms of typhoid fever were found, was one of the first on this subject.

CASE. A boy, twelve years old, after six weeks' illness with typhoid fever, died, apparently of a terminal pneumonia. At the autopsy the classic intestinal lesions of typhoid fever in a convalescent state were found, also broncho-pneumonia. The gall-bladder was full of pus and had several necrotic patches on the walls. Externally was a fibrinous exudate with adjacent peritonitis. The biliary ducts and duodenum were normal. The cause of death was cholecystitis, which had provoked peritonitis. Typhoid bacilli in pure culture were found in the pus and in the gall-bladder walls.

The author regarded his case as second to the one reported by Gilbert and Girode.

Chiari ¹⁹ made a further report to the International Medical Congress in Rome, giving the results of his examinations of 22 patients who died of typhoid fever. In three only were the typhoid bacilli absent from the gall-bladder. In 15 they were the only kind, and the number was often very great. Inflammation of the gall-bladder had occurred in 13 cases, in 12 involving only the mucous lining, in one the whole wall and causing a secondary peritonitis by extension. Chiari concludes that the occurrence of typhoid bacilli in the gall-bladder is the rule in typhoid fever, and that they increase and may remain there a long time; finally that they may cause gall-stones and relapse.

There are several questions of interest that suggest themselves in connection with these various reports, clinical and pathological:

- (1) How do the germs reach the gall-bladder?
- (2) Have they a special predilection for previously damaged gall-bladders or those containing gall-stones?
- (3) Is it probable that typhoid fever may cause gall-stones?
- (4) What are the means available for diagnosis and treatment?

CHANNEL OF INFECTION.

The sterility of normal bile is not questioned so long as the ducts are pervious and the flow is free, but when there is disease of the biliary passages by which the bile current is checked, micro-organisms from the duodenum find easy access to the gall-bladder. Charcot and Gombault after tying the common duct in

animals found that the bile above the ligature was infected by bacteria within a short time. Numerous other observations have confirmed this, and Létienne ²⁰ examined the bile immediately after death in forty-two patients who died of various diseases finding micro-organisms in twenty-four, or more than half. The bacterium coli commune was often observed, but there seems to be no reason why this germ should not always invade the gall-bladder after death. Naunyn ²¹ found it in the fluid removed during life in several cases of recent cholecystitis.

Whether in typhoid fever and in other infectious diseases there may be a stagnation in the bile-current and a vitiation in quality, as suggested by Harley, that allow the ready invasion of intestinal germs, or whether this may be preceded by a catarrhal cholecystitis engendered by the passage of the typhoid bacilli through the portal circulation, cannot be easily determined. Both channels are open. It has been shown experimentally by Pisenti ²² that the amount of bile secreted is diminished from one-half to two-thirds during septic fever in animals, and the same tendency may be assumed to be present in some degree during typhoid fever.

As to infection through the blood-stream, it is held by Sherrington ²³ that "though the blood be teeming with micro-organisms none can escape through the normal hepatic tissues, and it is only when the latter have been damaged by toxins in the blood, formed by the life of the bacteria, that the tissues allow the germs to pass through them." Experiments by Blachstein ²⁴ and others showed that after the intravenous inoculation of animals with the typhoid bacillus the gall-bladder in numerous instances was infected ten or twelve days later. In two rabbits these organisms were found to be very active in the bile after very long periods, from three to four months.

It is a matter of common observation that the bacilli of typhoid are voided with the urine, which they must reach, according to the observations of Flexner, ²⁵ through the glomerular capillaries, and there appears to be sufficient proof that the hepatic secretion is contaminated in a similar manner through the portal circulation. The suggestion of Chiari that germs may pass directly through the intestinal wall to the gall-bladder cannot be substantiated although the fecal odor is probably thus imparted.

Therefore we must conclude that infection of the gall-bladder takes place by the passage of micro-organisms through the biliary ducts with the supplementary agency of a contaminated blood-current.

RELATION OF GALL-STONES TO ETIOLOGY.

Recent studies (Naunyn, ²¹ Courvoisier, ⁶ Brockbank, ²² Mayo Robson ²⁶) leave no doubt that gall-stones render the biliary ducts and gall-bladder more receptive to infecting microbes, especially if either the common or the cystic duct is obstructed. The presence of calculi in a typhoid-fever patient would undoubtedly favor the occurrence of accidents from severe gall-bladder infection, and this is substantiated by the post-mortem evidence in some of the cases previously cited, since about one-fourth of the patients who died with typhoidal cholecystitis were found to have gall-stones. But in the great majority of cases no calculi were present and no evidences of previous local lesions. Moreover, several were in childhood, more in the adolescent period of life, when gall-stones

are comparatively rare. Therefore it may be assumed, in view of Chiari's discovery of Eberth's bacillus in the gall-bladder at nearly all his typhoid autopsies, that the pre-existence of gall-stones is not an essential feature in the infective process.

TYPHOID INFECTION AS A CAUSE OF GALL-STONES.

There is more ground for the supposition that typhoid fever, through gall-bladder infection, may be an important factor in the etiology of gall-stones.

Bernheim²⁷ suggested this sequence, stating that he had seen three or four times veritable accessions of biliary colic in the course of typhoid fever in subjects who had never had such attacks before. "May not typhoid fever," he asks, "produce alteration or stagnation of bile and thus determine the formation of gall-stones?"

The prolonged vitality of the typhoid bacillus within the body is well known and is instanced by the two cases previously cited, in which pure cultures were obtained from the gall-bladder in patients who came to operation for calculous cholecystitis five and eight months respectively after the termination of the fever.

A similar report by Chautemesse²⁸ relates to a case of grave typhoid with slow convalescence. Six months later, after an interval of perfect health, biliary colic appeared for the first time with icterus from obstruction. Surgical operation. Gall-stones. Pure culture of typhoid bacilli from the gall-bladder.

Especially interesting as bearing upon this point is the communication of Dr. Dufourt, of Viehy,²⁹ on "The Role of Typhoid Fever in the Etiology of Biliary Lithiasis." Nineteen patients with gall-stones had their first attacks of colic after severe typhoid fever. These attacks came on as early as the second month after the fever in two cases; in the third month in six cases; in the fourth month in three; and in the fifth month in one; while the remaining five dated their first symptoms at ten months or later after recovery from the fever. Such cases may be classed with the so-called "hepatic typhus" of French writers.³⁰

Whether the micro-organisms may cause a chemical precipitate in the gall-bladder from which cholesterol calculi are formed, or whether the bacilli themselves act as nuclei, is a matter for further study, but stagnation of bile, an important factor in stone formation, may be assumed to be present in typhoid fever. Naunyn states that he has found micro-organisms in the centre of a few bilirubin-calcium calculi, but this is very exceptional.

REINFECTION AND RELAPSE.

Chiari thinks that the possibility of re-infection through the intestine by bacilli from the gall-bladder should be considered. The occurrence of relapse in typhoid is an arbitrary matter and inexplicable. The belief that it is caused by the resumption of solid food *per se* is untenable. In certain cases the gall-bladder becomes a stagnant reservoir of typhoid bacilli, so to speak, under conditions favorable to prolonged and virulent activity. Therefore it is by no means impossible that an increase of food, by exciting a stronger flow of bile, may send back to the intestine a new growth of organisms which in turn cause those exacerbations and relapses that are often attributed to errors of diet.

PATHOLOGICAL CHANGES.

The pathological changes that have been noted involve the gall-bladder, the ducts and the peritoneum. The cholecystitis may be catarrhal with an exudate which at first is mostly serous. In other cases it is entirely purulent. Ulcers, often multiple, are found chiefly at the fundus, but they may cause perforation at the neck or elsewhere. Abscess involving the wall alone has been observed and in some instances the gall-bladder is destroyed by gangrenous inflammation.

In many cases the ducts have been free, with little evidence of cholangitis. In others impacted gall-stones were found, and jaundice is mentioned not infrequently. It cannot be supposed that great distention of the gall-bladder occurs without obstruction, although this may not be apparent after death if rupture has taken place. Brockbank³¹ states that "the cystic duct is curved like the letter S in its course between the neck of the gall-bladder and its junction with the hepatic duct, and pressure on it from a full gall-bladder, whether the fulness be caused by calculi or fluid only, will, at times, obliterate its lumen and induce further collection of the secretion of the wall of the gall-bladder with consequent dilatation of the latter."

When this obstruction is the result of pressure or of inflammatory thickening, the cystic duct may again become patent. But when the duct becomes impervious and takes "the appearance of a fibrous cord," the lumen is entirely obliterated by adhesive inflammation.

In many of the cases cited it has been noted that the fluid confined within the gall-bladder was pale, semi-serous, of low specific gravity, and lacking the usual appearances and chemical constituents of bile. This change, by which the gall-bladder secretion replaces the bile, goes on somewhat rapidly after the stoppage of the cystic duct.

A localized peritonitis may be induced by contiguity even when there is no perforation, and if rupture occurs later the escaping fluid may be limited to the right hypochondrium by adhesions between the liver, abdominal wall and transverse colon.

CLINICAL AND DIAGNOSTIC FEATURES.

In turning to the clinical aspect of gall-bladder infection it is apparent that, although we must believe that many or most cases of typhoid fever present bacteriological evidence of such infection, the symptoms caused thereby are seldom of importance; but on the other hand, the inflammation may reach such a degree of severity that life is cut off without warning of the local danger. In more than half the cases recorded, either through the latency of the symptoms, or on account of typhoidal stupor, nothing unusual was observed. Thus the gall bladder may become distended or perforation may occur without detection.

The subjects are mostly young, and childhood is not exempt from this complication. Several cases under ten years of age have been reported.

Those instances in which this condition can be determined during life present fairly diagnostic symptoms. They are: pain in the region of the gall bladder and under the scapula; a palpable, very tender swelling that is dull on percussion, sometimes pear-shaped and visible, giving a doubtful fluctuation, described in one instance, as like that of a tense hydrocele. "In gall-bladder inflammation," says Mr. Mayo Robson,³² "there is almost invariably a tender spot a little above

and to the right of the umbilicus, or, to be more exact, at the junction of the upper two-thirds with the lower third of a line drawn from the ninth rib to the umbilicus."

If perforation occurs, these symptoms are merged into those of collapse and general or local peritonitis, of which the source can only be inferred from its manner of development and the previous history.

The conditions to be excluded in diagnosis, in the more latent stages, are impacted feces, hydronephrosis, cyst, displaced kidney and appendicitis; and, when rupture of the gall-bladder has occurred, intestinal perforation. The distended gall-bladder gives more pain than either of the first three affections. A displaced kidney is movable, and the appendix is seldom found in the right hypochondrium. Collapse and peritonitis from rupture of the gall-bladder, as before mentioned and as observed in numerous cases, may be indistinguishable from these conditions when due to intestinal perforation. Marked leucocytosis would be suggestive.

PROGNOSIS.

The prognosis is unfavorable if the gall-bladder has become much distended or if deep ulceration has taken place, unless the symptoms can be promptly relieved. The local dangers in addition to those from the fever itself are very great. Among the cases that I have found reported one-quarter only got well, including those of post-typhoid cholecystotomy in which Eberth's bacilli were discovered at operation. Without doubt many cases of typhoidal cholecystitis recover spontaneously and go unobserved or unrecorded. But it is equally probable that others die in whom this state is unsuspected.

TREATMENT.

The indications are to relieve pain by opiates and local applications, hot or cold, to avert perforation if possible by absolute quietude or tapping the gall-bladder, and if rupture occurs or appears inevitable to resort to the promptest surgery.

I know of no case similar to mine in which typhoidal cholecystitis, as determined both clinically and bacteriologically at the height of the fever, has required immediate intervention. There may be others. Fortunately a simple tapping relieved pressure, opened the cystic duct and allowed escape for the sero-purulent fluid.

Had re-accumulation occurred, in the absence of peritonitis, expectant measures or tapping again would have been indicated, as the acute typhoidal state is a very unfavorable one for radical surgery.

In case of perforation and septic peritonitis, however, laparotomy should be performed as affording almost the only chance, but probably a better one than after intestinal perforation at the same stage of typhoid fever, because the inflammatory processes may be limited to the right hypochondrium, and the gall-bladder is a less vital part.

Such operations will be rare; but if done in the declining stage of the fever or during convalescence, the prospect of success is less unfavorable. A case of this kind, thus far the only one, I believe, was reported in the *Lancet* two years ago by Mr. Monier-Williams and Mr. Sheild.³⁵

CASE. A female, thirty-one years old, on the eleventh day of typhoid fever had sudden, severe abdominal pain with semi-collapse. The pain was

limited to the upper half of the abdomen, and was thought to be due to an intestinal perforation. The patient recovered from this complication, and became convalescent in the fourth week. The temperature was normal for a fortnight, when, at the end of the sixth week, there was another sudden, severe accession of pain and tenderness in the right hypochondrium at the hepatic flexure of the colon. Here a dull tumor appeared, the size of an orange. Again a diagnosis of probable intestinal perforation was made, and the condition was regarded as nearly hopeless. The next day there was slight rallying from collapse and a worse abdominal condition. Operation was decided upon. Median incision, extending later to the right, showed turbid fluid in the right hypochondriac region chiefly, but no perforation of the intestine. The gall-bladder was deeply inflamed, of a dark plum color, thickened, adherent and tightly distended. Near the neck was an ulcer the size of a three-penny piece, with a small perforation through which oozed the contents. The gall-bladder was opened and emptied of an ounce and a half of thick, offensive pus. There were no calculi. The patient made a good recovery. No satisfactory bacteriological examination was made.

From this study the following conclusions are drawn:

(1) The gall-bladder in typhoid fever is often infected by Eberth's bacillus, seldom by other organisms (streptococcus, bacillus coli communis).³⁴

(2) Fatal cholecystitis may result, the inflammation often involving the ducts (cholangitis), less frequently the hepatic parenchyma (abscess).

(3) Gall-stones predispose to this complication, and on the other hand there is ground for thinking that typhoid fever may determine the formation of calculi in predisposed subjects.

(4) The gall-bladder may be a focus for systemic re-infection.

(5) Diagnostic symptoms sometimes indicate the necessity for evacuating the gall-bladder by tapping or cholecystotomy.

ILLUSTRATIVE CASES.

1. Recovery. Leudet (Hagenmüller, *op. cit.*).

Female, thirty-six years. Fourth week, pyriform tumor in right hypochondrium, disappearing in ten days, reappearing at intervals during seven weeks. No jaundice.

2. Recovery. Griesinger (Hagenmüller, *op. cit.*).

Female, age twenty. Sixth week, peritonitis, slight icterus. Painful tumor to right of umbilicus. Swelling of liver. Collapse. Convalescence. In eighth week sudden return of tumor, with chills, icterus, vomiting. Later, two more relapses. Recovery fifth month.

3. Recovery. Laveran (Hagenmüller, *op. cit.*).

Man, age twenty-three. Painful symptoms and tumor in region of gall-bladder in sixth week.

4. Martin-Solon (*Bull. Fac. de Méd. de Paris*, 1820-21, VII, p. 370-375).

Patient died of peritonitis, and twenty-five ulcers of gall-bladder were found. Previous illness not clearly typhoid fever. *Enterite* (?).

5. Husson (*Bull. de la Soc. Anat.*, 1835, p. 104).

Child, eight years. Died at end of third week. Perforated gall-bladder. Cystic duct obliterated and converted into fibrous cord.

6. Dumoulin (*Gaz. Méd. de Paris*, Third Series, Tome II, 1848, p. 551).

Man, age nineteen. Third week, constant nausea and vomiting. Enormous tumor in right hypochondrium, extending to left of umbilicus and into right iliac fossa. Resistance like tense hydrocele. Liver raised. Upper limit line of right nipple. Diagnosis: distended gall-bladder.

Repeated chills suggestive of hepatic abscess. Coma. Death on 16th day. Autopsy: Typical intestinal lesions of typhoid; tumor, size of head, containing two litres of greenish bile; no gall-stones; adhesions with liver, transverse colon, etc.

7. Archambault (*Bull. de la Soc. Anat.*, 1852, p. 90).

Infant. On 30th day, signs of intestinal perforation. Death 12 days later. Perforation of gall-bladder. Localized peritonitis.

8. Barthez and Rilliet (*Maladies des Enfants*, Vol. II, second edition, 1853, pp. 5, 701).

Girl, age twelve. On 16th day, tumor in right hypochondrium that gradually disappeared. Death on 52d day. Autopsy: Perforated gall-bladder; circumscribed pus cavity between liver, stomach, gall-bladder and colon.

9. Ranvier (*Bull. de la Soc. Anat. de Paris*, 2 S., Tome VIII, 1863, p. 432).

Man, age twenty-eight. Died during convalescence in the fifth week. Autopsy: Limited peritonitis; perforated gall-bladder; right side of abdomen filled with yellowish, opaque liquid; walls of gall-bladder two or three millimetres thick and infiltrated with pus; a small calculus; Peyer's patches in stage of cicatrization. Author says he cannot explain this point of suppurative election, "si bizarre."

10. L. Colin (*Études clin. de méd. militaire*, p. 197, Paris, 1864).

Soldier. End of third week of rather mild attack; jaundice, gastro-abdominal pain. Death 11 days later. Autopsy: Peritonitis limited by transverse colon, liver and abdominal wall; gall-bladder size of goose-egg, perforated; no gall-stones; ducts pervious; typical intestinal lesions.

11. C. E. E. Hoffmann (*Zerstörung der Gallenblase bei Typhus*, *Virchow's Archiv*, 1868, XLII, 219-222).

Female, age twenty-five. Sixth week, jaundice. Eighth week, sinuses discharging through abdominal wall. Twelfth week, death. Autopsy: Destruction of gall-bladder; abscess beneath liver, containing 12 gall-stones; lesions of typhoid.

12. O. W. Foot (*Enteric Fever, Abscess in Walls of Gall-bladder*, *Irish Hosp. Gaz.*, Dublin, 1874, II).

Female, age thirty-two. Died in eighth week. Small abscess between coats of gall-bladder, communicating by a narrow orifice with interior. Extensive adhesions of abdominal wall. One cholesterol calculus, 23 grains.

13. Bürger (*Typhus abdom. mit Perforat. der Gallenblase in die Bursa Omentalis*, *Deutsches Archiv. für klin. Med.*, Leipzig, 1873-4, XII S., 623-630).

Man, age forty-one. Twelfth day, pain and tumor size of apple in region of gall-bladder. Gradual increase in size. Chills. No jaundice. Death from peritonitis in fifth week. Perforation of gall-bladder. Adhesions forming cavity filled with pus. No gall-stones. No abscess of liver.

14. P. L. Legendre (*Bull. de la Soc. Anat. de Paris*, Fourth Series, Tome VI, 1881, p. 193).

Female, age thirty. In second week peritonitis in right upper abdomen. Death 12 days later. Autopsy: Perforation of gall-bladder; pus in peritoneal cavity; three gall-stones.

EMPHYEMA OF THE ANTRUM OF HIGHMORE.

A NEW OPERATION FOR THE CURE OF OBSTINATE CASES.¹

BY HOWARD A. LOTHROP, A.M., M.D.,
Assistant in Anatomy, Harvard University.

In order to understand the conditions involved in these cases, we must, first of all, give our attention to the necessary anatomical details connected with this region, and then note the pathological changes which may arise, for such an understanding is of indispensable value in the treatment of antral empyema.

ANATOMY.

The Antrum of Highmore is a nearly closed cavity, occupying the whole of the body of the superior maxillary bone, pyramidal in shape, and presents three surfaces, an apex and a base. The apex is directed toward the malar process of this bone, its base corresponds to a large portion of the outer wall of the nasal cavity, and of the three surfaces, the superior forms the floor of the orbit, the anterior presents towards the face, and the posterior presents towards the zygomatic fossa. The posterior surface is the thickest, the base is the thinnest. Of the borders of the pyra-

¹ Read before the Boston Society for Medical Improvement, February 8, 1897.

mid, that formed by the junction of the base and facial surface is broadest and most important; it corresponds to the alveolar process of the superior maxillary bone.

When the soft parts are in place, the antrum is easily accessible through the canine fossa, which is external to the canine ridge, and is a common site for entrance in operative cases, but if the opening is made well to the outer edge of this fossa towards the ridge which descends from the malar process, exploration is even more satisfactory. The orbital and zygomatic

which is high up anteriorly under the inferior turbinate bone. When the soft parts are added it opens a little lower, but it is well protected from injury. The line of attachment of the inferior turbinate bone is roughly horizontal with a marked convexity upwards in the centre, while the partition below it, corresponding to the inferior meatus, is always more or less convex toward the antrum. This partition below the inferior turbinate is roughly oval in shape, as seen in Figs. 4 and 5. The size and shape of the antrum vary accord-

surfaces do not concern us particularly in the present consideration. The base or nasal surface must be considered in detail. The nasal bony wall of the superior maxilla is perforated by a large opening divided horizontally by the inferior turbinate bone, above which is the middle meatus, and below is the inferior meatus of the nasal cavity. The opening into the middle meatus is made smaller by the palate bone posteriorly and divided vertically by the uncinate process of the ethmoid, thereby leaving two bony framina

between the nasal cavity and the antrum. Below the inferior turbinate, the bony partition is made complete by the superior maxillary and palate bones and the maxillary process of the inferior turbinate bone. This partition is generally very thin and can be readily broken by a strong knife, but inferiorly it becomes thicker where it joins and separates the floor of the nasal cavity and antrum, so that here a small chisel may be needed to remove it. A groove on the inner surface of the superior maxillary bone is made into a canal by the lachrymal and inferior turbinate bones, so as to form the lachrymal duct, the bony opening of

ing to the concavities, convexities and thickness of its walls, and, although no two antra are exactly alike, it is unusual to find an abnormality which interferes seriously with most of the operative procedures undertaken for the relief of empyema of the superior maxillary sinus. The alveolar process is most marked in adults, but, in the aged after the loss of the teeth, it atrophies and may almost entirely disappear. All the walls of the antrum become much thinner and more brittle in advanced life.

The inner surface of the antrum is smooth for the most part, but along the borders, particularly the alveolar border (often called the inferior surface on account of its breadth), there are elevations and septa of greater or less prominence. The roots of the molar and bicuspid teeth, particularly the first and second molars, are commonly represented by bony elevations. The septa strengthen the bone and occasionally form separate compartments.

A mucous membrane with ciliated columnar epithelium lines the entire cavity, except at the ostium maxillare where it is continuous with the nasal mucous membrane. It frequently forms folds and pockets. Compared with that of the nose, it is much thinner, provided with fewer glands, and consequently much less able to absorb products of exudation retained within the cavity. Normally the ratio of secretion on the one hand, and absorption and evaporation on the other are nicely balanced, so that fluid does not collect within the antrum. Periosteum separates this lining from the bone. The blood-supply is derived from the sphenopalatine artery and numerous anastomosing branches on all sides of the antrum, but all of these arteries are of small diameter from which hemorrhage can be easily controlled by gauze packing.

The dental nerves are derived from the second division of the great trigeminal nerve, and pass along bony canals or semi-canals to reach the teeth. In the posterior wall are the nerves for the molar teeth, those for the bicuspid and incisor teeth are on the facial

surface anterior and laterally. Along the orbital surface is the infraorbital nerve, and also on account of the thinness of this plate of bone and the proximity of the orbit, this surface should be curetted with the greatest care. There are no nerves to be avoided on the nasal wall of the antrum.

The natural opening of the antrum, the ostium maxillare (looking from the antrum towards the nose), is seen to be on the nasal surface generally close up to the orbital surface and is usually of sufficient size to admit a large probe (Figs. 1, 2, and 4). The antrum, therefore, is a comparatively large cavity with a small outlet almost at its highest point. Before considering the nasal aspect of this opening, a word will be necessary concerning the other sinuses accessory to the nasal cavity.

The frontal sinus is so situated that its opening

Fig. 4.

leads from its lowest point into a canal called the infundibulum, thence into a groove called the hiatus semilunaris. The infundibulum and ostium frontale are of sufficient size to drain the frontal sinus readily, and inflammatory products are retained only when the passage is obstructed. The ostium maxillare opens into the hiatus semilunaris. The ethmoid sinuses are made up of numerous small cells located along the junction of the ethmoid and frontal bones, and are divided into anterior, middle and posterior sinuses. The anterior cells open near the bulla ethmoidalis above and in close proximity to the hiatus semilunaris. All of these openings, therefore, are close together, and are concealed more or less under the middle turbinate bone. The openings of the other ethmoid cells and the sphenoidal sinus are more distant and do not concern us at present. Such is the usual mode of opening of these sinuses.

The researches of Zuckerkandl and other anatomists and an examination of about fifty antra, with the kind permission of Professor Dwight of the Harvard Medical School, show that variations from the so-called normal type are common. As shown by the probe, the antrum and frontal sinus are frequently in direct communication through the infundibulum; again, the ostium frontale may have no connection with the

infundibulum, and open anterior to the hiatus semilunaris. The opening of the anterior ethmoid cells is at a variable distance from the ostium maxillare, and the latter may be supplemented by an accessory opening. The ostium maxillare is very constantly of small size, but Zuckerkandl pictures a case (Fig. 3) where the greater part of the nasal walls corresponding to the middle meatus were deficient, thus making the antra large recesses of the nasal cavity. Occasionally the ostium maxillare is the size of an ordinary lead pencil. These common anatomical variations go to show that these accessory nasal cavities are more or less in intimate relationship, which is of great importance in the consideration of the pathology of these sinuses. Experiments by Dr. F. C. Cobb show that fluids injected into the frontal sinus very frequently drain into the antrum and Dr. Fillebrown

Fig. 5.

has demonstrated this association by means of the probe, and, on the other hand, numerous antra have been examined by the writer where fluid can be made to gravitate into the frontal sinus from the antrum.

The object of this detail is to show that collections of pus may spread from one sinus to the other by the law of gravity, according to the position of the head, which is constantly changing, as in walking, stooping or lying down. In that the antrum is usually the lowest of the sinuses most of the time, it is found most commonly to contain pus, but whether of primary or secondary origin will be considered later.

ETIOLOGY.

Empyema of the antrum may be of primary origin, as the result of fractures of the superior maxilla or as the result of tumors and foreign bodies within the antrum, but these are unusual causes.

As a rule, however, most cases are consequent on the extension of inflammation either from the alveolar process or the nasal cavity, but it is impossible to determine the percentage of each with any degree of accuracy. Most of the cases discovered by the dentist are of alveolar origin because he is visited on account of trouble with the teeth. The nose specialist finds that inflammation extending from the nasal

cavity is more often the cause of empyema of the antrum. As examples, we have the direct *extension* through a patent ostium maxillare consequent on catarrhal nasal conditions, or the inflammation is consequent on *obstruction* of the ostium maxillare by polypi and hypertrophies.

There is but little clinical evidence to show that antral empyema is often secondary to frontal empyema, for the latter is rare, and the former comparatively common. That antral empyema often, if not usually, accompanies frontal empyema (when this latter does occur), is shown by the statement of Zuckerkandl that post-mortem, he has never found a case of frontal empyema uncomplicated by antral empyema. This view is further strengthened by the anatomical variations and experiments just mentioned showing that the antrum may act as a *reservoir* merely. If such is the case, the pathological changes consequent on *retained pus*, and the great chronicity and often danger in treating frontal empyema, demonstrate the uselessness of daily *antral* irrigations, and the value of *obliterating the antrum, as a large pus receptacle*, with its annoying and disagreeable consequences.

Less is known about the relation between ethmoid and antral empyema. There is no direct communication between these sinuses, but undoubtedly pus flowing over the ethmoid bulla in excess, could enter the ostium maxillare or reach the ostium frontale if the head happened to be in the right position. While, on the one hand, the position of the ostium frontale is such that drainage from the frontal sinus is perfect, and there is every reason to believe that this sinus should remain healthy unless its canal is obstructed by hypertrophies or polyps, on the other hand, the drainage from the ethmoid cells is never perfect, hence when once thoroughly involved, it is questionable whether many of these obstinate and even dangerous ethmoid cases, ever recover. Be that as it may, even here as in frontal cases, if the antrum is involved secondarily to an ethmoid empyema, first as a *receptacle* for pus and then, in consequence, generating pus from its own walls, *its cavity as such should be obliterated*.

SYMPTOMS.

Of the symptoms of chronic suppuration of the antrum, suffice it to say at this time, that *subjectively* the patients have but little to complain of provided drainage is free. The ever annoying and intensely disagreeable symptom is the intermittent escape of foul smelling pus in more or less profusion from the anterior or posterior nares, according to the position of the head.

COURSE.

The course taken by cases of empyema of the antrum is generally very chronic. Some few are relieved within a few weeks, some last months or years, and others are never cured. Relapses are very frequent, and amelioration may last only so long as irrigations are continued. Satisfactory statistics of results are difficult to obtain. Of 58 cases treated by Chiari, twenty-seven were cured (hardly 50 per cent.), and the remainder more or less benefited. Hajek says that "it is certain that frequently, in spite of the absence of complications, affections of the antrum are not cured." Acute cases and some of the sub-acute cases undoubtedly resolve spontaneously, and irrigation relieves many chronic cases and benefits others

temporarily, but of the very chronic cases (and they are comparatively numerous) it is questionable whether more than 50 per cent. are permanently cured.

DIAGNOSIS.

Suffice it to say that pus issuing from the middle meatus should lead us to suspect empyema of one of the accessory nasal cavities — antrum, frontal or anterior ethmoid — but differentiation from this sign alone should never be conclusive. Transillumination is often of value, but is frequently deceptive. The surest sign is the aspiration of pus through the inferior meatus, a procedure carried out with but little pain under cocaine anesthesia, and with no attendant risk. The needle should just penetrate the wall of the antrum as near the floor of the nose as possible, and the head tilted laterally with the suspected antrum uppermost.

PATHOLOGY.

When the mucous membrane of the antrum is acutely inflamed, it becomes congested and edematous followed by cell desquamation, and round-cell infiltration in the superficial layers. There is then an accumulation of mucus or muco-pus in the antral cavity. After a certain length of time resolution takes place, or the exudate becomes more turbid and finally purulent, and then the deeper layers become involved. The vessels and lymphatics are no longer able to absorb the exudate, which then overflows into the nasal cavity as pus. Gradually the round cell infiltration travels deeper and deeper, until finally, in very chronic cases, the periosteum is invaded. In consequence, more or less of the lining of the antrum is hypertrophied, its epithelium exfoliated and replaced by granulations, and its glands destroyed. The surface is pigmented and ecchymosed, and may be studded here and there with small retention cysts. In the periosteum, bony plates and spicules are often formed, which eventually may assume considerable proportions.

Such is the catarrhal condition which may be primary, or secondary to one of the following causes:

- (1) Syphilis — commonly accompanied by necrosis.
- (2) Foreign bodies.
- (3) Malignant disease.
- (4) Tuberculosis.
- (5) Polypi.
- (6) Periostitis — from caries of teeth or alveolar process.
- (7) Dentigerous cyst.

The longer the suppuration exists, the greater and more permanent are the lesions to the lining membranes of the antrum. The constant irritation of retained pus prevents spontaneous resolution and hinders or may even preclude eventual recovery under most careful and frequent irrigation. The granulations become very exuberant and must be removed mechanically, and be replaced by scar tissue.

TREATMENT.

Our attention will be directed to the treatment of chronic cases, and, before attempting to seek for the causes of prolonged treatment or frequent relapses and failures, let us consider briefly the present methods adopted for the relief of empyema of the antrum. It is taken for granted that, as far as possible, all probable causes have been removed, namely: that the nasal cavity has been carefully examined, polypi and

hypertrophies removed, particularly from the vicinity of the ostium maxillare, and the catarrhal conditions ameliorated; that the question of empyema of the other sinuses has been considered; that the alveolar process has been thoroughly examined with reference to carious teeth or diseased alveolus; and finally that the question of syphilis has been eliminated.

After the removal of possible causes, one of the following modes of irrigation is usually resorted to:

- (1) Through the ostium maxillare.
- (2) Through the artificial opening in the (a) alveolar process, (b) canine fossa, (c) inferior meatus.

Most of the literature devoted to the treatment of chronic antra is made up of the consideration of which of these methods is the most rational and gives the best results. Every operator has his favorite site for entrance to the antrum, and he is naturally inclined to believe that the best results are to be obtained by the method which he has chosen. However, when one compares a large number of statistics reported by different observers, the results from these different methods are not at great variance. All have rapid and brilliant cures, all have cases which yield only after months of regular and patient irrigation, and all meet with nearly an equal number of cases which are only ameliorated temporarily or fail to improve. Now there must be some underlying cause for this unanimity of results which seems to be explained as follows:

To repeat, the antrum is a comparatively large bony cavity with a small opening near its upper surface, which always remains more or less patent in chronic cases, otherwise acute symptoms arise. In perhaps fifty per cent. of all cases it is possible to irrigate through the natural opening, other cases may be made accessible by removing various obstructions. By this route the walls of the antrum remain intact. The other modes of irrigation require that an artificial opening shall be made, namely, through the alveolus, the canine fossa or the inferior meatus. These openings are comparatively small, or if made large, they contract rapidly, and consequently, in order to keep them open any length of time, they must be tamponed. Hence, directly after each irrigation, the artificial opening is closed and remains so until the next irrigation, so that it makes no practical difference from a *therapeutic* standpoint where the canula is introduced for irrigation. From the standpoint of ease and convenience of access there is an undisputed choice of procedure, but this question need not be considered here.

Irrigation, therefore, under these apparently different methods, is practically one and the same process, and, on account of the anatomical structures of the antrum, more or less of the irrigating solution remains behind after each washing, the artificial opening is closed, and pus begins to re-accumulate at once. The retained solution soon loses its antiseptic power, becomes warm and forms a nidus for the growth of micro-organisms, and the antral mucous membrane is subjected to the irritation of pus and organisms for many hours. *Nevertheless* many cases recover under this treatment which is sufficient to help Nature restore the parts to their normal condition. These are the cases where the inflammation is of comparatively short duration or the pathological lesions superficial.

Then follow more radical measures. The canine opening is enlarged even to admit one or two examin-

ing fingers and the antral wall curetted, and the cavity packed with medicated gauze. This method is successful in many of the obstinate cases, but, as a rule, the opening becomes small and then tampons must be resorted to if the disease is not already cured, and at once free drainage no longer exists, and the frequent relapse occurs. Many operators favor this method which undoubtedly yields good results, but the objections are the constant drainage into the mouth, the occasional persistence of an antral fistula, and injury to the anterior dental nerves.

Spicer, of London, is still more radical and combines this extensive opening in the canine fossa, together with a deep groove down the alveolus, with the method of Krause, that is, he makes one or two perforations into the antrum from the inferior meatus by means of the Krause trocar, the finger introduced through the canine opening to serve as a guide. This latter is to serve as an accessory opening and he strives to maintain a permanent opening in the canine fossa. No artificial measures for drainage are used and the patients are directed to irrigate the antrum thrice daily, and force air through from the nose to the mouth. This procedure is made use of in obstinate cases, many of which are cured where the milder methods have failed. He states that many of the most obstinate cases have been cured in from four to six weeks. Other operators have been able to cure cases which have remained obstinate for a long time under alveolar irrigation, as soon as they have combined with it a counter opening made by the Krause trocar through the inferior meatus. The secret of the success of the more radical operation which has been made use of only as a last resort, is undoubtedly due to the establishment of better drainage. Such is the present status of antral surgery, and results show that there remains much to accomplish.

Now no one will dispute the facts that empyema of the antrum is often a most obstinate affection, that many cases last for months or years, and that, finally, certain cases last a life-time. In considering suppurative conditions in general, there would seem to be no reason why cases should not recover if the part is accessible to the surgeon, if pathological formations are removed, and if thorough or even permanent drainage be established if necessary, provided such causes as tuberculosis and malignant disease are eliminated, both of which are unusual causes of the disease in question. The problem with which we have to deal in these cases is that of a rigid bony cavity which retains the products of exudation under conditions where the activity of the local blood-vessels and lymphatics is insufficient to bring about resolution. In general, cavities containing pus should be opened, pathological products removed, and free drainage established and maintained until a cure is reached.

As examples we may cite the following:

In empyema of the thoracic cavity, we have a resistant bony wall partially surrounding the pus collection, and the rest of the circumference made up of soft parts, as lung or diaphragm. So long as free drainage is maintained the lung slowly expands, the visceral and parietal pleura become adherent and the abscess cavity is gradually obliterated; then the case is well.

In the rare cases of suppurative pericarditis, recovery can take place only on obliteration of the pericardial space, which presupposes free drainage.

Ordinary pus collections in soft parts get well after

the pus is evacuated and the collapsed walls become adherent, which again presupposes free drainage, although small collections may be absorbed.

Cavities in the larger bones get well in a somewhat similar way except that the walls are rigid and cannot collapse; hence small cavities are filled with granulations and then healed over, and large cavities leave deep scars or holes into which the epithelium slowly creeps, with marked resultant deformity.

Now how does the antrum differ from the problems just presented? It can be drained, and, indeed, from many different points; it is too large to fill with exuberant granulations with the hope of obliterating a suppurative cavity; its walls are rigid and it must always remain a cavity. It need not, however, in obstinate or apparently incurable cases of empyema, remain a closed cavity, surgically speaking.

The object of this communication is to suggest that, for the cure of these obstinate cases, the nasal cavity and the antrum be made one by the removal of the greater part of the partition below the line of insertion of the inferior turbinate bone, thus making the antrum a recess from the nasal cavity with a large permanent opening, so that the future retention of pus can never occur; also its object is to suggest a technique and instruments for the accomplishment of this procedure.

In the first place it will be asked: Are there any objections, *a priori*, against the removal of so large a portion of the nasal wall of the antrum? It occasionally happens that the ostium maxillare is of large size, so that a very free atmospheric communication is established; Zackerkandl pictures a case (Fig. 3) where there is a deficiency of the whole partition above the inferior turbinate, probably of congenital origin, comprising at least half of the nasal wall, and finally it is no rare occurrence for large openings to follow the destructive lesions of syphilis. None of these cases suffer any consequent discomfort. Fresh air circulates freely, the cavity is not exposed to the direct current of air, and the few particles of dust, etc., need cause no more trouble than in the more sensitive nasal cavity. The inferior turbinate bone serves as an excellent protection from catarrhal products coming from above. It is yet to be decided whether acute inflammations of the nasal cavity would extend more readily to the antrum, but even if they did, the nature of the walls of the antrum and its large outlet would preclude obstruction, allow a prompt resolution, probably without having given rise to any subjective symptoms whatever.

A further argument showing the practicability of this procedure and the unimportance of the antrum as a separate cavity, is the occurrence of the antrum as a very small cavity or its very occasional entire absence. In all of these cases with small antra, the inferior portion of the nasal cavity is proportionally just so much wider, so that deep recesses are formed on either side.

OPERATION.

The following technique is based upon observations and operations on about fifty antra. Before operation each individual case must be examined carefully by means of mirrors, probes, palpation, etc., in order to obtain as exact a knowledge of the size and shape of the antrum as possible.

The problem consists in removing the greater part of the partition below the inferior turbinate bone,

which covers most of this partition so as to conceal it from view. The plane of this partition is roughly vertical and parallel to the inferior meatus which makes it more difficult to approach. The Mikulicz and Krause instruments are curved appliances for puncturing a small hole, and their use may be so interfered with by the inferior turbinate that a portion of the latter must be removed. In order to meet all emergencies, two instruments have been devised, whereby this whole partition can be removed without injuring or disturbing the inferior turbinate bone. We are to work through the anterior nares, hence the extent of motion allowed is somewhat limited. These instruments consist of a hooked knife and a curved chisel.

Knife (Fig. 6). The handle is of large size in order to allow a firm grip to be obtained, the shank is oval, strong, and nearly straight, but a slight curvature at the junction of shank and handle, allows an unobstructed view when introducing it into the nares, and adjusting it under the turbinate. The blade is hooked, parallel with the flattened handle and points toward the depressed lower end of the handle so that its precise direction is known at all times. The hook is thick in order to give strength and is made sharp in front so that it will cut when pushed ahead. This sharp edge continues around the blunt point, up the concavity of the hook and about three-quarters of an inch along the lower edge of the shank. In that thin bone is to be cut, the edge must not be very sharp and not be approached by a very acute angle.

Chisel (Fig. 7). In certain instances, the bony partition is too thick to be removed along the lower edge by means of the knife, but this can be quickly accomplished by means of a chisel devised after this pattern. It is flat so that it can be used equally well in either nostril, and has a double curvature as per diagram. The cutting edge is concave, so that it will not slip off the narrow plate of bone, and is at right angles to the long axis of the shaft which is square on section so as to serve as a guide to the direction of the cutting edge. The cutting edge terminates by two sharp points (*a* and *b*) which will readily penetrate a layer of bone. The naso-antral partition is on a deeper vertical plane than the opening of the nares, hence the chisel is curved in order to penetrate this partition quite anteriorly (Fig. 8). The chisel is introduced

parallel to the nasal septum with the point *a* lowest which is then lowered and directed under the inferior turbinate so that the concavity on the side of the chisel *c* fits closely to the outer bony wall of the nares with the point *a* close to the floor of the nose. Of the fifty cases examined, this procedure never failed to give access to the antrum at the desired point. The concavity of the cutting edge now serves to guide the chisel along, which should be advanced about an inch when it will be seen that the concavity *d* directs the handle of the chisel across the line of the nasal septum (Fig. 8). Then withdraw the chisel and re-introduce it in a similar manner with point *b* lowest until the cutting-edge meets the point to which the chiselling had ad-

vanced. The handle is now observed to be parallel with the nasal septum and the chisel can be advanced to any depth (Fig. 8). An examination with the probe suitably bent will quickly determine whether the use of the chisel will be necessary or not. A normal or hypertrophied inferior turbinate bone need not be disturbed, but if it reaches too low it is easily tilted up toward the septum by the various movements of the knife. The operator must be thoroughly familiar with the local anatomy and know what is being done by every movement of the instruments.

STEPS OF OPERATION.

Profound Anesthesia.—Application of cocaine to inferior turbinate will increase the operating space, lessen hemorrhage during operation, which is then controlled by tampon before the influence of the cocaine is gone.

Patient seated upright in a chair with head held horizontally in the natural position.

Posterior nares of affected side plugged by means of Bellocq's sound or a catheter, to prevent escape of blood into pharynx.

Head mirror to be worn by operator, facing a well

lighted window, which is sufficient to guide the introduction of instruments. These are manipulated by the sense of touch, and the general direction of cutting edges as shown by the position of the handles.

Before removing the partition in question, the operator must decide upon the probable condition of the lining membrane of the antrum, whether the duration and symptoms lead him to suspect the presence of exuberant granulations or other pathological formations. Of course conclusions can be only suppositious, but if the antrum is to be curetted, this object is best accomplished by an opening made at the outer edge of the canine fossa well toward the malar process of the superior maxilla. The walls are comparatively thin so that the opening need not be large, and is best made by a conical burr-drill worked by hand. The opening is to be made of just sufficient size to admit the curette, which also allows of exploration of the antrum by the probe. Most of the pathological changes are along the lower half of the antrum which can be curetted with impunity. Great care should be used in curetting the orbital surface.

If called for, the preliminary canine operation is best done first, on account of hemorrhage which is more extensive from the nasal operation. The canine opening is to be closed at once after the operation, or may be used for thirty-six or forty-eight hours as an entrance for tamponing the antrum if necessary.

Introduction of Knife.—This is accomplished by holding the blade parallel to the nasal septum with the point lowest; when well within the nasal cavity the point is guided under the inferior turbinate until it reaches the outer wall of the nose and the blade is now flat on the floor of the nose. Force is then exerted until the point perforates this partition and the shank prevents more than the point from entering the antrum. The knife is then pulled forward horizontally until it meets the bony resistance due to the thickening at the junction of the nasal and facial surfaces, and then pushed backward along this incision, and continued until the general resistance is met at the junction of the nasal and zygomatic surfaces. We now have a horizontal incision along the lower boundary of the inferior meatus at the posterior end of which is the knife-blade in a horizontal position. The handle is now rotated so that the point is directed downward and the knife carefully pushed into the antrum which makes a vertical cut, and breaks this lower posterior angle of the partition into the antrum. Now rotate the handle so that the point of the knife is uppermost and the cutting edge of the concavity fits into this vertical cut. With the knife in this position (point directed up and towards the orbital surface, which is too far distant to be injured) the vertical cut is lengthened a little and then the knife drawn forward just below the curve of the insertion of the inferior turbinate bone for about an inch, then the point is rotated so as to be directed downward, and the cut continued obliquely downward and forward so as to meet the anterior end of the primary horizontal incision (Fig. 5). Before removing the knife, the point (which is directed downward) is rotated in an arc down and out toward the nasal cavity and thus it is often possible to force the severed partition out into the inferior meatus whence it is easily removed by forceps. The knife is not to be used as in cutting soft parts, but is to be drawn or pushed with slow steady pressure aided by slight prying movements, and the bone is felt to crumble as

advance is made. It happens often that no large piece of the partition can be removed at once for many small fragments may result which cling loosely to the circumference of the incision. The opening, however, has been accomplished and these fragments are removed easily by means of forceps and curette. The probe will now determine whether the ridge below need be removed by the chisel or not, and the probe must be constantly used to determine very accurately how much of this partition has been removed. It is always well to enlarge slightly the lower posterior angle with the chisel.

There are no important structures to be injured by this procedure. The edges of the incision are protected behind, in front and below by resistant bony boundaries, and above, the insertion of the body of the inferior turbinate seems to guide the knife along without injury. The nasal duct opens at the upper anterior angle under the oblique surface of the turbinate and is easily avoided. The duration of operation need not exceed fifteen or twenty minutes. The parts should now be thoroughly irrigated, in order to remove clots of blood and fragments of bone and mucous membrane, and packed with iodoform gauze, either through the canine opening or that in the inferior meatus, as the case may require. The gauze is to be removed in thirty-six to forty-eight hours.

CONVALESCENCE.

The antrum is to be irrigated with a warm four-per-cent. boric-acid solution two or three times daily, a procedure which can be carried out by the patient after the first few days. A syringe with the nozzle properly curved is introduced just within the anterior nares and the whole antrum is flooded easily by a properly directed current. After the first few days the patient can continue his business as ever. In some cases the small nasal mirror can be introduced through the large opening and the walls of the antrum inspected. This can be done in almost all cases on removal of a small portion of the inferior turbinate. The whole wall of the antrum is accessible to treatment by applications on a properly curved probe. A view of the nasal wall of the antrum after this operation on the cadaver, obtained through a sagittal opening made by removal of a portion of the orbital and facial surfaces (Fig. 4) will convince the observer that the antrum will never again serve as a reservoir for pus.

CONCLUSIONS.

That the relation of the openings of the accessory nasal cavities is not constant, and that fluid may gravitate from one to another according to the position of the head.

That the antrum is a reservoir for pus, of primary or secondary origin.

That many cases of empyema of the antrum are never cured, therefore further efforts are needed which must be in the line of surgery.

That the more radical operations with the idea of drainage have relieved cases hitherto incurable.

That there are important objections to a large canine or alveolar opening with the idea of establishing permanent drainage.

That permanent nasal drainage is less objectionable than oral drainage.

That the removal of the lower half of the naso-an-

tral wall prevents further pus retention and thereby allows the antral mucous membrane to resume a healthy condition.

That the operation suggested is of short duration and not severe although most radical.

That, by this procedure, the antral cavity is rendered easily accessible to frequent irrigations by the patient and to local applications and occasional inspection by the surgeon.

THE AMERICAN PEDIATRIC SOCIETY'S REPORT ON THE COLLECTIVE INVESTIGATION OF THE ANTITOXIN TREATMENT OF LARYNGEAL DIPHTHERIA IN PRIVATE PRACTICE,

WASHINGTON, MAY 4, 1897.

In this second and supplementary investigation, the aim has been to ascertain: (1) What percentage of cases of laryngeal diphtheria recover without operation under antitoxin treatment; (2) What percentage of operated cases recover. The report now submitted may properly be limited to answering these two inquiries.

Since the beginning of the general use of intubation, no disease has been more thoroughly observed and more fully reported than laryngeal diphtheria. Operative cases, especially, whether ending fatally or favorably, have been fully and promptly put on record. The result has been a collection and tabulation of cases available for control, such as few diseases offer. There are thousands of intubation cases before the days of antitoxin, and thousands since, available for comparison. It is, then, to cases of laryngeal diphtheria, especially those requiring operative interference, that we may apply the crucial test of the value of the antitoxin treatment.

Sixty thousand circulars containing the following questions have been distributed:

Age of patient?

Diagnosis confirmed by:

- (1) Presence of other cases in the family?
- (2) Appearance of membrane elsewhere?
- (3) Bacteriological cultures?

How many days and parts of a day after the first appearance of the disease was antitoxin first administered?

How many doses of antitoxin were administered?

Dose of each injection in antitoxin units?

Whose antitoxin used?

Non-operative cases — evidence of disease:

- Hoarseness?
- Aphonia?
- Stenosis?

Operative cases:

- (1) Intubation? On what day?
- (2) Tracheotomy? On what day?
- How long, in days and fraction of a day, was tube in the larynx or trachea?

Sequelæ (in recoveries):

- (1) Broncho-pneumonia?
- (2) Paralysis?
- (3) Nephritis?

Death, cause of, and on what day?

- (1) Broncho-pneumonia?
- (2) Extension of membrane to the bronchi?
- (3) Sudden heart paralysis?
- (4) Nephritis?
- (5) Sepsis?
- (6) Accidents of operation?

Recovery?

Remarks, especially on fatal cases?

These circulars were distributed throughout the United States and Canada, the following means being employed: contributors to first report, members of the Society acting as agents for their respective localities, boards of health, local medical societies and antitoxin

manufacturers. At the outset, in this connection it is a pleasure to acknowledge that the labors of the Committee have been much lightened by the uniform good-will of all addressed, more aid coming spontaneously than in the previous investigation. It is also a pleasure to especially acknowledge the Society's indebtedness for efficient aid in distributing circulars and securing returns to H. K. Mulford Co., Parke, Davis & Co., Lehn & Fink (Gibier's), the Health Departments of Chicago, St. Louis, New Orleans, Denver, San Francisco, Boston, Washington, Buffalo, Providence, Ann Arbor, Newark, Montreal, Toronto and others.

To the New York Health Department is due the thanks of the Society for every possible courtesy in distributing blanks and, through their inspectors, of securing returns of operative cases.

In order to reduce sources of error it was desirable to bring together a large number of cases, from widely distributed localities, from many different observers and operators, and for a period of time including all seasons of the year. All returns have been examined by the Committee, and only such cases accepted as bore satisfactory evidence that they were first of all diphtheria, and secondly that the lesion had invaded the larynx.

A total of 1,704 cases of laryngeal diphtheria are ours for present study. A few cases (228) had not satisfactory evidence that there was laryngeal involvement; indeed, some were reported through misunderstanding the fact that only laryngeal cases were wanted, and a few were reported in which there was no mention that antitoxin was used. These cases are, of course, not included in the number referred to above. Of the 228 cases, 218 recovered, 10 died.

In a total of 1,704 antitoxin-treated cases of laryngeal diphtheria, there was a mortality of 21.12 per cent. (360 deaths).

TABLE OF ALL CASES SHOWING AGE AND RESULT OF TREATMENT.

	Fatal.	Recov.	Totals.	Mortality.
1 year and under,	25	35	60	41.66%

Over 20 years,	5	17	22	22.72
Unknown	0	4	4	..
	260	1,344	1,704	21.12%

CASES NOT OPERATED ON.

The first inquiry of the circular was what percentage of cases of laryngeal diphtheria recover without operation under antitoxin treatment.

Of 1,704 total cases, 1,036 were not operated upon (60.79 per cent.). Of these, most did not require operative interference, a few cases were thought to require it, but operation was refused. All cases are included, and it will be noted, there are no eliminations.

Among the 1,036 cases not operated on, there was a mortality of 17.18 per cent. (deaths 178) or, to answer the inquiry of the circular exactly, of 1,036 cases not operated on, 82.82 per cent. recovered (or 858 cases).

As good as is this percentage of recovery in so large a number of cases of diphtheria of the severest type, it is believed it is not as good as it ought to be. Cases of laryngeal diphtheria not requiring operation, according to the testimony of consulting intubationists, are

seldom heard from a second time, and less often find their way into reports. It was formerly estimated that about 10 per cent. of cases of laryngeal diphtheria recovered without operation. The present report shows that in 1,036 cases 82.82 per cent. recovered.

CASES OPERATED UPON.

In analyzing this class of cases, it is believed a more exact conclusion as to the value of the antitoxin treatment can be arrived at than in the non-operative.

There will be entire harmony of opinion as to the severity of laryngeal diphtheria which requires operative interference. In the early days of intubation it was customary to speak of the percentage of recoveries, and 25 per cent. and 27 per cent. were considered good results. In the last report the recoveries had crept up so high in the one hundred cases, that it seemed more natural to speak of the percentage of mortality.

In this connection it is interesting to inquire what were the best reliable statistics of intubation, taking cases as they occurred, without selection, in pre-antitoxin days. In 5,546 intubation cases collected by McNaughton and Maddren in 1892, the mortality was 69.5 per cent., or, to bring the facts into line, 30.5 per cent. recovered.

O'Dwyer's personal experience, in private consultation, brings us more nearly face to face with the old-time experience with diphtheria. Note that the following 500 cases came under the observation and care of one practitioner, a skilled operator, extended over a dozen years of time, and therefore included all types of the disease.

Exclusive of the first 100 cases of intubation, which he (O'Dwyer) regards as experimental, the results stand as follows:

Second 100 intubations,	27 per cent. of recoveries
Third 100 "	30 " "
Fourth 100 "	26 " "
Fifth 100 " (which only reached 70)	27 " "

Total percentage of recovery 27.56 per cent. When he had reached 70 on the fifth hundred something occurred which carried the phraseology up over the divide so that it was appropriate to speak of percentage of mortality. At this point in history, antitoxin arrived and interrupted forever the old series. In O'Dwyer's next 59 cases the mortality was 14 deaths or 23.7 per cent.

In a total of 1,704 laryngeal cases there were 668 cases operated upon. In the 668 there were 182 deaths, or a mortality of 27.24 per cent. In the former report, in 553 intubated cases the mortality was 25.9 per cent. In approximate figures there is a difference between 27½ per cent. and 26 per cent.

SUMMARY.

Sixty thousand circulars were distributed throughout the United States and Canada.

Time allowance, the eleven months ending April 1, 1897.

Whole number of cases in this report, 1,704; mortality, 21.12 per cent. (360 deaths).

The cases occurred in the practice of 422 physicians in the United States and Canada.

Operations employed:

(a) Intubation in 637 cases; mortality 26.05 per cent. (166 deaths).

(b) Tracheotomy in 20 cases; mortality, 45 per cent. (nine deaths).

(c) Intubation and tracheotomy in 11 cases; mortality, 63.63 per cent. (seven deaths).

Number of States represented, 22, the District of Columbia and Canada.

Non-operated cases, 1,036, 60.79 per cent. of all cases; mortality, 17.18 per cent. (178 deaths).

Operated cases, 668, or 39.21 per cent. of all cases; mortality, 27.24 per cent. (182 deaths). Two facts may be recalled in connection with this paragraph. First, that before the use of antitoxin it was estimated that 90 per cent. of laryngeal diphtheria cases required operation, whereas, now, with the use of antitoxin, 39.21 per cent. require it. Second, that the percentage figures have been reversed, formerly 27 per cent. approximately representing the recoveries, while, now, under antitoxin treatment, 27 represents the mortality. To put it in other words, before the use of antitoxin, 27 per cent. recovered, now 73 per cent. recover, and this in the severest type of diphtheria.

The present report will strike many members of the Society as revealing a mortality a little too large in each of the two classes. The mortality is large, larger than the personal experience in private practice of many would expect.

The reasons for this are (1) that antitoxin is still used too late, either from procrastination on the part of the physician, or objection on the part of the friends; or (2) in a half-hearted way which shows itself in doses from one-tenth to one-fourth as large as they should be. In truth, both the physicians and the friends of the patient are timid.

This report, it must be admitted, shows too large a mortality. In the opinion of the Committee it is a larger mortality than will ever be shown again. Antitoxin is gradually being used earlier in the disease, and it will soon be used in sufficient doses.

To the Society, the Committee desire to say that they have sought to carry out their wishes in putting antitoxin on trial, to accept no testimony that did not bear the stamp of reliability, that they have employed the methods approved in the case of the first investigation and report, and that they have confined their work to definitely answering the main questions which the Society and profession now have in mind. Points that were settled in the first report and have since been corroborated by general medical literature, are not again taken up.

If the Committee are asked to put forth the three most valuable points established in this eleven months' work, they are:

First. The mortality of laryngeal diphtheria at present rests at 21.12 per cent.

Second. That 60 per cent. approximately have not required intubation.

Third. That the mortality of operated cases is at present 27.24 per cent.

W. P. NORTHRUP, M.D.
JOSEPH O'DWYER, M.D.
L. EMMETT HOLT, M.D.
SAMUEL S. ADAMS, M.D. } Committee.

THE COMMITTEE RECOMMEND:

ANTITOXIN should be given at the earliest possible moment in all cases of suspected diphtheria.

QUALITY.—Of the products on the market some have, by test, been found to contain one-half to one-third the antitoxin units stated on the label. Select the most concentrated strength of an absolutely reliable preparation.

DOSAGE.—All cases of laryngeal diphtheria, the patient being two years of age or over, should receive as follows:

First dose—2,000 units at the earliest possible moment.

Second dose—2,000 units, twelve to eighteen hours after the first dose, if there is no improvement in symptoms.

Third dose—2,000 units, twenty-four hours after the second dose, if there is still no improvement in symptoms.

Patients under two years of age should receive 1,000 to 1,500 units, the doses to be repeated as above.

Clinical Department.

FRACTURE OF HUMERUS FROM BALL-THROWING, WITH SKIAGRAPH.

BY CHAS. F. WITHINGTON, M.D., BOSTON.

W. R., a healthy, well-developed boy of fifteen years, of rather exceptional muscular development, was in the act of throwing a golf-ball to the farthest possible distance. It was an over-hand throw, and just as the ball was leaving the hand he felt a sharp snap in his arm, which immediately dropped powerless

to his side, and could not be again moved. Examination readily showed crepitation in the upper segment of the right humerus.

For the accompanying skiagraph I am indebted to the courtesy of Dr. Francis H. Williams. It was made just two weeks after the injury, and in taking it

the apparatus was removed so as to allow the arm to rest down to its full extent directly upon the plate. The character of the fracture was thus well brought out, and the case is put on record to illustrate the split fracture which may be produced by over-powerful action of the throwing muscles. It also shows incidentally the as yet ununited epiphysis.

A CASE OF AN ANOMALOUS CONSTRICTING RING ABOUT THE GLANS PENIS.

BY CHARLES F. PAINTER, M.D., BOSTON.

IT has been my fortune during the past year to have under observation a patient about thirty years of age suffering from time to time with extremely painful erections of the penis due to a rather anomalous condition, at least a condition not described in any text-book to which I have had access.

The subject is a man in good general health, with a clean venereal record. His genito-urinary apparatus had never caused him any trouble until about one and one-half years ago, when he became annoyed by painful erections on awakening. In the lax condition of the organ the foreskin retracted perfectly freely, but if erection took place with the glans covered, great pain resulted, with inability to retract, or at least with great difficulty; and if by chance it was retracted, strangulation from paraphimosis was not infrequently threatened. On one or two occasions active measures had to be resorted to in order to avert this catastrophe.

On examination the penis was of normal size, and nothing unusual about its appearance and contour was noted. There are no cicatrices on the glans or on the surface of the prepuce at any point. The organ was not observed in erection, but the patient says that the penis is not bent or twisted in any way in the state of erection as they are sometimes by cicatricial contractures. The prepuce is of normal size covering the glans naturally, and moves easily over it. It is his habit to wear the prepuce forward. When the glans is covered there is to be felt in the subcutaneous tissue over the corona or a trifle posterior to that, not in the glans or the corpora of the penis, a rounded fibrous ring which completely encircles the penis. This ring is one-eighth of an inch in width, and can be picked up in the fingers though adhering more or less closely to the subjacent tissue. The skin of the penis moves freely over it. It is of the same feel throughout its entire extent. In the small triangle on the under surface of the glans formed by the frenum are some quite prominent veins, evidently slightly varicose from the obstruction to the return of the blood by this constricting band. All the pain and difficulty in retracting the prepuce at the time of erection is referred to this triangle. This band evidently acts passively as a constrictor as the penis becomes larger during erection and produces this varicosity.

Not wishing to circumcise if I could avoid it, I made two or three incisions parallel to the ring directly over it and then incised it by transverse incisions. The ring cut like dense fibrous tissue. This gave relief lasting for a period of two months or so, when the old trouble returned. The incisions all united firmly and the ring feeling precisely as before. This same proceeding was undertaken September 24,

1896, with a similar result — immunity from troublesome symptoms for two months, with a return at the end of that time.

February 15, 1897, a half-inch of the ring was dissected out on the left side of the penis, beginning at the frenum, and the wound closed with continuous catgut. On the 24th of February the stitch had separated out and a portion of the incision was closing by granulation. As before all painful symptoms had disappeared. The varicosities beside the frenum were not noticed, and it was hoped that enough had been removed so that they would not recur. Unfortunately the tissue removed was not examined microscopically. Grossly, it had the appearance of tough fibrous tissue.

The text-books make no mention of anything at all comparable to this condition. Dennis and Morrow speak of certain gouty conditions in which there are asymmetrical masses in the body of the penis which produce similar symptoms and great distortion of the organ during erection, a condition not at all comparable to this. The other authors referred to are Treves, Keyes, Park and Taylor.

In the catalogue of the Surgeon-General's Library I could find no reference to any such condition except possibly one case reported by Bouissan in the *Gaz. Méd. de Paris*, of 1857, which unfortunately I could not investigate except by title.

Thiery, in 1892, reported in the same journal three cases of what he calls constricting valves of the prepuce, which, however, differ from the above in that they were not continuous, were in the anterior part of the prepuce proper and were congenital. These three cases occurred in several thousand examined for that purpose at the Hôpital du Midi.

Marmot, in 1893, in the *Bulletin of the Anatomical Society of Paris*, reports five cases of the same condition in 10,000 cases examined. The constricting bands due to inflammatory conditions are not uncommon, but present different features from those noted in the case now reported.

A more or less hasty study of the recent volumes of the "Index Medicus" threw no further light on the subject. The case is reported on account of its apparent rarity, which doubtless may not find confirmation in the wider experience of others.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

REGULAR meeting, February 8, 1897, the President, DR. A. L. MASON, in the chair.

DR. HOWARD A. LOTHROP read a paper entitled:

EMPYEMA OF THE ANTRUM OF HIGHMORE: A NEW OPERATION FOR THE CURE OF OBSTINATE CASES.¹

DR. FARLOW: If Dr. Lothrop has devised an operation which will cure some of these very obstinate cases, he is deserving of the greatest credit. On account of its somewhat formidable character and because of the undesirability of having a large cavity in direct communication with the nose, where crusts would form and collect, it is, of course, only to be tried after other and milder measures have failed. If the inferior

¹ See page 455 of the Journal.

meatus is small and the bony wall to be cut somewhat thickened, I should think the procedure might be rather difficult in the living subject. It remains to be seen whether it has advantages over the multiple punctures with breaking down of the intervening bone, a method practised somewhat in severe cases.

DR. COOLIDGE: It will be interesting to watch clinically the results of this very ingenious operation. The kind of case in which it would be applicable would be one in which other methods had been tried first. I think we should hesitate before throwing into the nasal cavity such a large cavity as the antrum. I cannot agree that where this has happened as a result of syphilis the patient does not suffer. The patient may suffer if the cavity is enlarged by any process. The mechanism of secretion is delicate and if too much air enters the nose we may get scabbing, dryness of the mucous membrane and discomfort.

As a rule, empyema of the antrum gets well under any effective method of washing or drainage after the cause of the empyema is removed and not before. In a case in which there is no hope of removing the cause, and the sinus is acting as a reservoir for pus, this permanent opening would afford relief, especially if it can be made without creating secondary disturbances in the nose.

DR. CLARK: I have been very much interested in Dr. Lothrop's paper. I think he has presented the subject of the treatment of antral disease in a very thorough way. He has certainly shown considerable ingenuity in the invention of instruments so applicable to the anatomical requirements of the operation he describes. In a case of simple antral disease I should be inclined to try first every other well recognized method of treatment before resorting to this as it is an unproved method. I should even be inclined to try first a large temporary opening in the canine fossa and packing with gauze. Of course, there are cases in which this measure fails and a permanent large opening into the nose is preferable to one into the mouth. In cases of disease of the ethmoid cells, which is a region every nasal surgeon knows is a dangerous one to deal with, where all reasonable treatment has failed and where the antrum is evidently a reservoir for the pus coming from that region, it seems to me such an operation as this might be useful in preventing the accumulation of pus in the antrum so that the small amount of pus coming continuously from the ethmoid cells would have no place to accumulate and thus cause little discomfort. In ethmoid disease where the antrum is a reservoir the principal discomfort is caused by the periodical discharges of large amounts of more or less foul-smelling pus. If the pus had no place to accumulate it could not acquire any odor.

DR. COBB: I have very little to add. It seems to me one disadvantage of the operation, possibly, is the inability to see the contents of the antrum as clearly as in the canine fossa operation. Polypi in the antrum or roots of necrosed teeth can be seen by the canine operation very easily and then the origin of the pus is plain. Of course, it is very easy to wash through the canine fossa. Whether leaving a cavity below the turbinate would produce a whistling sound in breathing, I think is a question of some interest. There would be a wall of bone over which the air would draw more or less. The question arises as to whether the physiological swelling of the turbinates which takes place in respiration would be interfered with by remov-

ing the wall in such a way that the air could draw through the diseased antrum all the time. It seems to me that in most intractable antral empyemas we shall probably find that the cause of the trouble is dependent on other cavities and as our knowledge of dealing with these other cavities improves we shall find that the antrum will get well. I have cases operated on by various men which, after as long a time as a year or fourteen months of constant pus in the antrum, have got entirely well without touching the antrum (by simply clearing out the ethmoid region). I think this shows that the changes in the antral wall are not perhaps as chronic as we were led to expect. I think the method the reader has suggested of doing this operation is very ingenious and for empyema due to any local cause ought to be of benefit.

DR. LELAND: I would like to congratulate Dr. Lothrop on the valuable paper which he has presented. It is understood, I suppose, that this operation is only to be used as a last resort, and I am the more inclined to approve of it since it is in the line of my own thought for some time past. After having seen the unsatisfactory results from the Mickulicz's operation, and after having seen the long and tedious suffering after the operation through the canine fossa, wherein the treatment accompanied by much discomfort has to be continued through one or more years, I have been led to think that there ought to be some method of entering the antrum and producing complete drainage, which would be more comfortable for the victim of the disease. It was my privilege to see Dr. Jansen, of Berlin, do a number of operations through the canine fossa, and to see some upon which the operation had previously been done at various intervals. The extreme swelling of a painful cellulitis immediately following the operation, the disagreeable packing of the cavity, the wearing of the obdurator, devised by him, for a couple of years or more after the operation — all of which has been described by him in one of the early numbers of Fränkel's "Archives"² — combine to make a picture which we would desire to have our patients avoid.

It seemed to me possible that the cavity could be explored and cleared of its contents, be it polyps, or the remains of teeth, dermic cysts, or other foreign material, through an opening in the canine fossa and then by passing points properly curved through the bone in the lower meatus, a part could be mapped out which could easily be removed, working through both openings, namely, the nose and the canine fossa; the wound in the front wall could then be allowed to close immediately, which, of course, would make the danger of reaction on the face less. But this operation has not been tried; I have been waiting only for a favorable case. Now this operation of Dr. Lothrop's has been presented and I think it much better than the one which I have been considering.

But it seems to me that perhaps we are too anxious or too ready to adopt radical measures in these cases. It is strange that a rigid cavity of this size has been made in the body with an opening at the top which, of course, controverts all our ideas of drainage; there must have been some wise provision for this cavity to take care of itself and it has been suggested by some author that the drainage is carried on when necessary

² Zur Eröffnung der Nebenhöhlen der Nase bei chron. Eiterung. A. Jansen: Archiv. für Laryngologie u. Rhinologie, Erster Band, Heft 2, S. 135.

on the principle of siphonage, promoted by the air currents as they come through the nose, especially as they come through the middle meatus. It has therefore seemed rational to direct our first efforts, even in the most obstinate cases, to the restoration of this drainage; therefore, it has been my object in the treatment of all cases of empyema of the accessory sinuses to clear the second meatus and, in fact, to reduce all swellings, remove all tumors, be they bony or soft, from the nose, in a word, to restore the anatomy to as near normal as possible. Of course this does not produce a complete cure in a short time in these chronic cases, but I have learned not to be discouraged if the patient continues to have more or less discharge through a series of years.

I have a case in mind which came to me about twelve years ago with a chronic purulent disease of the right antrum. After clearing out the polyps and reducing the swellings, the nose got into a very satisfactory condition, but, of course, the discharge from the antrum did not cease; I used all my powers of persuasion to induce the patient to be operated upon after Mickulicz's method, but was unable to do so. I saw him again from four to six years afterwards when I found his nose perfectly clear, no discharge and no subjective symptoms of disease of the antrum.

I have since carried out the idea suggested to me by this case and have determined to resort to no radical operation such as the one to-night advocated except as a last resort when the life of the patient has become intolerable.

I would, therefore, congratulate Dr. Lothrop on his valuable contribution to this branch of the subject, the diseases of the upper air-passages, and hope that we shall have from him reports of his success in carrying out this procedure.

DR. LOTHROP: Of course this method is devised merely for obstinate cases. Regarding when to operate, and when to give up the ordinary methods, that is a difficult matter. When the patient is tired of the irrigations which are continued month after month with practically little change in the discharge, I think it is fair to try this operation. As regards the operation being a formidable one, it seems to me that it is far less severe than the extensive canine operation. In the latter you have a great deal thicker wall of bone to go through and many soft parts to disturb. After almost every extensive canine operation there is considerable edema of the cheek, there is almost invariably more or less sepsis, and pus burrows not rarely down the cheek. When the operation is as extensive as Spicer advises (where he obtains permanent drainage), this is brought about by the removal of a considerable part of the anterior wall of the antrum which encroaches on the alveolar process; this is followed often by very troublesome disturbances in the teeth. Then, again, the patients he has operated upon complain of constant discharge into the mouth through this canine opening. In the operation suggested, the soft parts disturbed are not very extensive, and the total area of cut-surface is very slight compared with that of the canine operation. Many operations for deviated septa, and hypertrophied turbinates where you remove the lower portion of the inferior or middle turbinate, are attended with greater mutilation than this would cause as it appears on the cadaver. Concerning the whistling sound, that can be determined by examining some of the cases where the partition is gone as result of syphilis. I

have not noticed any observations on that question. If the empyema is a consequence of disease in other cavities and the antrum acts merely as a reservoir and the source cannot be reached, it seems to me it will be advantageous to obliterate this pus-retaining cavity. Surely some ethmoid cases will never be cured on account of the proximity to the base of the brain where the bony wall is almost paper-thin. Frontal empyema is also obstinate and as far as I can find both frontal and ethmoid are even more obstinate than antral.

ASSOCIATION OF AMERICAN PHYSICIANS.

TWELFTH ANNUAL MEETING, WASHINGTON, D. C.,
MAY 4, 5, 6, 1897.

THE meeting was called to order by Dr. J. M. DA COSTA, President. Dr. Da Costa then delivered

THE PRESIDENT'S ADDRESS.¹

DR. GEO. B. SHATTUCK, of Boston, then read a paper on

THE SERUM TEST IN TYPHOID FEVER.

These tests were made in the pathological laboratory of the Boston City Hospital by the medical house-officers, under the supervision of Dr. T. Leary, of the pathological department. The clinical statements necessarily vary on account of the unavoidable peculiarities of hospital practice. Thus the date of the beginning of the fever is assumed to be the time when the first constitutional symptoms appear, but the patients not always being intelligent the records are not always exactly correct. All the tests were made with liquid blood. In the laboratory a longer maximum time limit (an hour) was allowed for the reaction than some observers consider justifiable. Room cultures react less promptly than the thermo-tat. Of these 145 cases, 125 were set down as typhoid fever, 19 not typhoid fever, and one doubtful, though reacting to a serum test. The cultures used at the laboratory were daughter cultures from the spleen of a patient who had died from typhoid fever. Room cultures had been used in most of the cases; and these cultures, while the organisms are fewer in number, are larger and more motile, and the reactions, while a trifle slower, are absolute. In the thermostat cultures there is often a small sediment of dead organisms, which, if shaken up into the fluid, may interfere with the diagnosis. The technique used is that commonly practised. A positive reaction was often obtained in much less than an hour's time; the bacilli had lost their motility and grouped themselves.

From the results of the test in 116 cases with the clinical diagnosis of typhoid fever, it was shown that reaction took place from the 6th day of the disease up to the 122d day. In 11 cases in which there was a doubtful diagnosis, four gave no reaction at any time. One of these was a case of meningitis; one of malignant endocarditis; the third and fourth were possible typhoid cases. In five of these cases the serum test gave the positive result, and was of material service in determining a doubtful diagnosis. In some doubtful cases the serum test gave both a positive and negative reaction on different days. In 18 cases with a clinical diagnosis other than typhoid fever, there

¹ See page 421 of the Journal, May 6th.

was no reaction in 15; and in three (one of which was pneumonia, one thought to be acute military tuberculosis, and one of exophthalmic goitre), the typhoid reaction was positive, and the diagnosis of typhoid was justified. It having been stated that negro blood was more prone than the blood from the white to produce the reaction even in the absence of typhoid fever, tests were made also with 13 colored patients, in eight of whom there was no reaction; in three there was a reaction more or less satisfactory, and in two there were good reactions. These two did not have typhoid fever while in the hospital, although what they had before they entered the hospital could not be positively affirmed.

The diazo reaction was sought for in 89 of the 125 cases of typhoid fever, and was found in 42, and not found in 47.

The following conclusions seemed justifiable:

(1) The serum reaction may be obtained towards the end of the first week of typhoid fever, but is both more pronounced and more usual later in the course of the disease.

(2) It may be present without relapse at the end of the fourth month.

(3) It may be absent one day and present the next.

(4) Of 125 cases of typhoid fever the reaction was absent in only one case. In two cases it failed, but there was in each only one test, in one case on the 12th and in the other on the 82d day.

(5) In 19 cases of other diseases clearly uncomplicated by typhoid, there was no reaction.

(6) In one case, where the diagnosis must remain doubtful, although typhoid cannot be positively excluded, there was a reaction.

(7) In a number of difficult and perplexing cases the serum test was of distinct service in establishing or correcting the diagnosis.

(8) This test will probably prove itself a useful aid to clinical diagnosis, and especially in hospital practice.

DR. A. C. ABBOTT, of Philadelphia, said that the conditions which surrounded this work in the City Board of Health were not so satisfactory as in hospitals, nevertheless the results in Philadelphia had been so far very good. Of 164 cases of dried blood, 115 had been examined; of 68 with the clinical diagnosis of typhoid fever, 66 gave a positive reaction; thus there were 2.9 per cent. failures; 23 developed in less than a week, and the longest time was 32 days. Two cases at first gave negative results, and on a second examination gave positive results; seven cases were doubtful at first and positive later; two cases gave a very meagre history.

DR. J. H. MUSSER, of Philadelphia, said there was one period when this reaction was confusing, and that was in the latest stages of the disease, when typhoid fever is a terminal infection. He related a case of meningitis preceded by typhoid in which the reaction was present and disclosed the condition.

DR. WM. OSLER, of Baltimore, said that 44 cases had been examined at the Johns Hopkins Hospital by Dr. Bloch, and the reaction proved satisfactory. In several cases the test was found very late in the disease. In one case the reaction appeared in a slight recrudescence of the disease; again in meningitis and in certain cases of remittent fever the absence of response to the test determined the diagnosis. Reaction is not usually found before the sixth day.

DR. HERMAN M. BIGGS, of New York, spoke of tests made with serum from cantharides blisters. He thought the ratio of serum to culture an important point.

DR. JAMES TYSON, of Philadelphia, said that the disease sometimes was aborted spontaneously; and he related a case of two young girls who went skating on the Schuylkill, and drank some of the water through a hole in the ice. Both had typhoid fever. One was well in a week, and one in three weeks; they both gave the reaction, though in a modified form. He mentioned one case of military tuberculosis. The case came on the 17th day of the illness, and was supposed to be typhoid fever. There were no signs of tuberculosis. The Widal test was negative, but he held to the diagnosis of typhoid fever. The autopsy showed a typical case of tuberculosis, with no signs of typhoid fever except the large spleen.

DR. FRANK BILLINGS, of Chicago, said that mistakes may occur, due to faulty technique. He thought that Dr. Wyatt Johnston had been misunderstood. He was made to say that an old culture could be used; but what he did say was that an old culture could be used as a basic culture from which the daughter-working cultures could be made. The technique should be well understood; for instance, as to the age of the culture, the proportion of serum to the culture, and other details. One case which he mentioned gave a positive reaction after three years, and Widal says that seven years is the longest time that he has heard of.

DR. JAMES T. WHITTAKER, of Cincinnati, related a case which early in its course gave first signs of Bright's disease and then of military tuberculosis. The reaction of Widal was perfect, the case went on to recovery and was found to be typhoid fever.

DR. F. C. SHATTUCK, of Boston, related a case in which there was first fracture of a leg, then some fever, 104°, and later albuminuria; and this was supposed to be Bright's disease. The reaction proved positive and the diagnosis was made of "nephrotyphus."

DR. E. C. JANEWAY, of New York, had seen the danger of trusting too much to the negative side of this test when early in the course of the disease. He had been called in more than once when the test was negative. In one case, on the 28th day of the disease, where there had been earlier a negative reaction, after collapse and intestinal perforation a positive reaction was obtained too late. A negative result does not deprive typhoid fever of its danger, and regarding the serum test as pathognomonic when negative results are obtained may be very misleading. The case may not be recognized as typhoid fever until too late. He had known of cases in which a diagnosis had not been made until the convalescence. We must be very careful in negative cases.

DR. A. LAWRENCE MASON, of Boston, then read a paper on

GALL-BLADDER INFECTION IN TYPHOID FEVER.²

The case began with an inflammation of the gall-bladder followed by a perforation and intestinal rupture as also complications of typhoid fever. In looking over the history of the subject he had found 40 cases which were first recognized at the post-mortem. His case was a woman, thirty years old, who in the

² See page 449 of the Journal.

third week of typhoid fever suffered from anorexia, vomiting and constipation. The reaction was positive; there was pain and tenderness in the right hypochondriac regions; swelling; the gall-bladder could be felt below the edge of the ribs; the liver dulness was normal. The pain became so intense that he aspirated the gall-bladder and drew off a quantity of brownish-looking liquid; the relief was immediate. There were no gall-stones found, the gall-bladder was resected, and the wound was packed with iodoform gauze. Recovery ensued. He showed some of the liquid, and also a photograph of the patient with the situation of the tumor outlined. A bacteriological examination of the fluid showed typhoid bacilli, and the serum reaction was positive. He inoculated rabbits with some of the fluid. Not many cases of recovery from this operation are on record. Rokitsansky and Frerichs have written the best histories on this trouble. He also quoted other authors. It is only in the past ten years that it has been possible to use bacteriological methods in investigating these cases. The typhoid bacilli were found in the biliary ducts; and in some cases gall-stones are found, but not many. Reinfection of the gall-bladder should be considered. Prognosis has been unfavorable if the gall-bladder is much extended. The treatment is to relieve pain and remove the fluid. Laparotomy should be necessary.

From his work he draws the following conclusions:

- (1) The gall-bladder in typhoid is always infected.
- (2) Cholecystitis may result.
- (3) Gall-stones predispose to this complication.
- (4) The gall-bladder may spread infection.

DR. WM. OSLER then read a paper on

THE HEPATIC COMPLICATIONS OF TYPHOID FEVER.

He considered the subject under the following headings:

- (1) The Focal Necroses.
- (2) Jaundice.
- (3) Abscess, which may be in the form of the suppurative pyelophlebitis, or as a solitary abscess.
- (4) Affections of the Bile-Passages, such as typhoid bacilli in the gall-bladder in typhoid fever, cholecystitis and cholangitis as complications and sequelæ of the disease, typhoid fever and gall-stones.

He spoke of the rarity of jaundice in these cases and said that in the first 500 cases in his practice at the Johns Hopkins Hospital there were only two instances of jaundice in this condition. Blachstein showed at the Hopkins that the bacillus typhosus could live for 15½ weeks in the bile-passages, and the colon bacillus for a longer time. In 14 cases in which the gall-bladder was affected, and which died, the typhoid bacillus was found in seven, and other organisms in the other seven cases. In these seven fatal cases there were no hepatic symptoms. There is a great possibility of infection in the gall-bladder, as the production of an acute cholecystitis without typhoid fever is possible from the records of the present day. He had seen a case in which there was a large amount of gravel. After a heavy meal of beefsteak and potatoes the patient the next day vomited the meal and the meal before it, became pale and anxious and cold, and had great pain and tumefaction in the right hypochondriac region. Dr. Hälsted operated, and found no bile, but stones and a yellow liquid in which the colon bacillus was found. Chiari's studies on this subject are made with great care. This condition is

very rare, there only being five found in 2,000 recorded in Munich. The number of recent cases is greater than is usually recorded. He then related four cases as follows:

CASE I. Typhoid fever. On the 27th day the colon bacilli was found during convalescence; subsequently the case recovered, though later the cholecystitis developed, the pain being in the right iliac region. Appendicitis was suspected and an operation was performed, but the appendix was not diseased. Then the gall-bladder was found adherent to the intestines and perforated, from which a yellow fluid was exuding. A serous fluid was removed and also a stone from the gall-bladder. The wound was packed with iodoform gauze, and the patient made a good recovery. This was a colon calculus.

CASE II. In the third week of typhoid fever she got better; later she came into the hospital, became jaundiced, gall-bladder was enlarged. Operation was performed; the gall-bladder was opened and drained, and the patient died.

CASE III. Had a fever for 82 days, with slight reaction, probably typhoid. Vidal's reaction was dubious. On the 35th day of the fever there was pain in the right hypochondriac region. Cholecystitis was found. The patient recovered.

CASE IV. Patient had had typhoid fever; got better, and was dismissed. Later she returned, complaining of pain in the right side, with headache and weakness. She looked healthy; there was a marked Vidal reaction. Later she was jaundiced; later she had parotitis.

DR. WM. T. COUNCILMAN, of Boston, spoke of the great frequency of typhoid bacilli in the gall-bladder; they are nearly always present there. The bacilli enter the gall-bladder from the blood; they are always in the liver, that is, practically always. There are very few organisms that get into the blood which escape the liver and from there they easily pass into the bile-vessels. He showed a very typical specimen of typhoid necrosis.

DR. JAMES TYSON, of Philadelphia, then read a paper on

UREA ESTIMATIONS IN CASES OF TYPHOID FEVER TREATED BY THE BRAND BATH METHOD.

He related a case of typhoid fever in the hospital. The third day after admission there was albuminuria, and hyaline casts were present. The diet was liquid, especially milk. Knowing the general prejudice against giving baths in this condition, he began on the fourth day to collect the urine, and found on the first examination 2.9 grammes of urea. During the bath the secretion of urea was markedly increased; the patient was tubbed five times in one day, and there was a large amount of urine and urea secreted. The secretion was full but fluctuating. Thus, on the 28th day of the disease, there were 2,100 c.c. of urine, with 29.8 grammes of urea; on the 29th day there were 2,100 c.c. of urine, with 24.7 grammes of urea; and on the 30th, 2,280 c.c., with 32 grammes. The albumin fell to one-twelfth of one per cent. of the bulk, and then disappeared entirely, and so did the casts. Expectoration was copious; the cough grew less, but no tubercle bacilli were present. There was an otitis media in both ears, but no defect in the hearing. The nephritis was mild, and was what Stockton would call an upper renal complication. Such a condition would not prevent him from using the Brand method when there is a rapid movement of the blood through the kidney; but this stagnation is dangerous, and therefore Brand's method does not do harm. He quoted some statistics to show the advantage of this treat-

ment. For instance, in a garrison where 138 soldiers had typhoid fever, 69 were treated by the Brand method, 5 had nephritis and all recovered; while of the 69 other soldiers who were not treated by the Brand method, 9 had nephritis and 5 died. As the patient was taking only milk, the source of the urea was easily found, and the amount of nitrogen ingested could be exactly analyzed, and would show how much was taken in and how much excreted, and the difference between that taken in and that secreted when obtained from tissue metamorphosis.

DR. GEORGE DOCK, of Ann Harbor, Mich., then read a paper on

CANCER OF THE STOMACH IN EARLY LIFE, AND THE VALUE OF CELLS IN EFFUSIONS IN THE DIAGNOSIS OF CANCER OF THE SEROUS MEMBRANES.

He reported a case of cancer of the stomach (scirrhous) in a man of nineteen years. There was extensive infiltration of the stomach, with early obstruction of the cardiac orifice. There was metastasis in the peritoneum and pleura with fatty ascites; later, effusion in the pleural cavities, first left, then right. In the various effusions were cells which, besides containing fatty granules and vacuoles, showed, in a large proportion karyokinetic figures, both typical and atypical. After a reference to the literature, a comparison was made with the findings in other effusions in serous cavities, tending to give to such cells a certain diagnostic value.

The paper was read in abstract, giving the salient points in the history and histological examinations, with demonstration of specimens and drawings. The patient had had typhoid, and after drawing off five litres of liquid no mass was felt. At the autopsy also a very small stomach was found, and there was no mass in the organs but in the serous membranes. He spoke of the early age of the patient and the character of the fluid, and said that we now know that cancer of the stomach occurs at an earlier age than was formerly supposed; but the disease runs a slower course and remains longer in the stomach than it does in older persons, so that it seems as if an operation should be urged. It is not easy to make a diagnosis of cancer by the cells alone, but it can be better made out when considerable portions of tissue are cut and examined.

DR. SIMON FLEXNER related a case that came into the Johns Hopkins Hospital. There was a large tumor extending into the intestines. Examination of the fluid showed no cells, but it was supposed to be cancer. A very careful study of the case showed it to be tuberculosis of the peritoneum.

DR. FRANCIS DELAFIELD, of New York, read a paper on

THE INFLAMMATIONS OF THE COLON.

The object of this paper was to describe the forms of colitis which ordinarily occur in New York, and to give the results of his experience as to the prognosis and the treatment. The paper was illustrated by micro-photographs. He spoke of the various kinds of dysentery; the simple acute, the climatic, the ordinary and the amebic. In the first kind there are no changes in the intestines: in the acute catarrhal colitis or dysentery. There were two varieties one of which was a mucous and one which was a serous condition.

The mucous variety is rarely fatal; there is sometimes bleeding; the cells are filled with mucus; the lymphatic glands are also swollen. The cause is not known. There are a variety of organisms found, but none in particular. This is probably due to impure drinking-water or impure milk, together with the high temperature of air and overcrowding. The principal symptoms are local. Little fecal matter passes; there is a rise in temperature. Some cases do not go to bed, and some do not even stop work. When the colon is affected it is worse still. Adults usually recover, but children often die. The treatment is rest in bed, careful diet, empty the colon, relieve the pain by opium, injections of weak infusion of flaxseed tea; many cases become chronic. There are no changes in the mucous membrane except a slight change in the epithelial coat.

In the serous variety there is a large exudation of serum, but this condition is not to be confused with the functional disturbance of the colon. This is not fatal, and he has never seen it post-mortem. This disease is common in New York, especially after hot weather, but occasionally occurs in the winter. Some persons are predisposed to it, and have it summer after summer. There is a feeling of necessity to empty the bowel, and the passages are considerable, as much as two quarts. A large number of cases get well under a variety of treatment, and some with no treatment at all, while others continue in spite of everything. The favorite drugs are opium, castor oil and salol. Here we have an infiltration of the connective tissue of the coat of the intestine; this is much thickened; there is an inflammation of the upper, rather than the lower parts of the intestines. The passages vary, and the disease may last from a few days to a year. The treatment is not satisfactory.

In the third variety there is an increased production of mucus and of serum and there are large numbers of blood-cells present; the inflammation is rather extensive; there are numerous small superficial ulcers which are not easy to be seen with the naked eye and the ulcers all have overhanging edges; he knows very little of the cause; the invasion is sudden or gradual and the cases vary in length, some being fatal in a few days and some running for several months. Treatment should be given early; milk diet, rest in bed, good food, dry climate, irrigation of the rectum, in the earliest stages, medication of opium, salol, castor oil.

Croupous or diphtheritic dysentery is familiar to all, and need not be further described. He showed some specimens obtained from dogs in which an artificial croupous dysentery had been set up by an injection of a strong solution of corrosive sublimate.

Amebic colitis is well known to us through the work of Councilman and others. There are two varieties, one with simple inflammation of the colon and another when ulcers are formed with overhanging edges.

DR. D. W. PRENTISS, of Washington, exhibited

TWO CASES OF ERYTHROMELALGIA.

Diagnosis, pathology and treatment were discussed with special reference to their relation to other diseases, classed as vasomotor. The treatment especially is worthy of note, since heretofore it has proved almost unavailing. It was hoped that other members would be able to add something in this direction, especially with reference to surgical interference.

(To be continued.)

AMERICAN PEDIATRIC SOCIETY.

NINTH ANNUAL MEETING, WASHINGTON, MAY 4, 5, 6, 1897.

THE meeting was opened by the President, DR. SAMUEL S. ADAMS, of Washington, who delivered an address entitled

THE EVOLUTION OF PEDIATRIC LITERATURE IN THE UNITED STATES.

In this address he reviewed in chronological order the various works on the diseases of children which have been written in this country during the past one hundred years. Every author writing upon this subject before 1870 was mentioned. Since that date the contributions have been too numerous to receive individual mention. The first definite contribution to pediatric literature was made by Dr. Rush in 1789, in a description of influenza. Following this were mentioned the names of Caldwell in 1796, Stenart in 1806, the American Matron in 1810, Jackson in 1812, Miller in 1814, and Logan in 1825. There were numerous contributions between that date and 1848, when J. Forsyth Meigs published his important work on the diseases of children, the last two editions of which appeared under the authorship of Meigs and Pepper. The next important name in pediatrics appeared ten years later, when Jacobi in 1858 wrote his first paper on children. It is also notable that J. Lewis Smith wrote his first paper on children in the same year. The first edition of his well-known work on diseases of children appeared in 1869. The most important names which have since appeared as the authors of systematic works are those of Keating in 1889, Starr in 1894, Sachs in 1895, Rotch in 1895, Holt in 1896.

Dr. James C. Wilson read a paper on Tic Convulsif, and reported a case which belonged to the class of nervous diseases which includes the "jumpers" described by Beard.

Dr. B. Scharlau presented a synopsis of fifty-six cases of Empyema operated upon during 1896 with very favorable results.

Dr. W. D. Booker reported a case of Congenital Diaphragmatic Hernia associated with recurrent attacks of asthma dyspepticum. During one of these attacks the child died and the true pathological conditions were revealed by the autopsy.

Dr. J. P. Crozer Griffith reported two cases of Unilateral Tremor in Children.

Dr. J. Henry Fruitnight read a paper on a Frequent Significance of Epistaxis in Children. He believed that this symptom was frequently the result of cardiac disease and should always receive full attention.

Dr. George N. Acker reported two cases of Meningitis, apparently tuberculous in nature, with recovery.

Dr. Joseph O'Dwyer reported a case of Congenital Stenosis of the Larynx, in which relief was obtained by gradual dilatation with steel sounds.

Dr. William Osler read an extended paper on Adherent Pericardium in Children, and reported cases.

Dr. A. Jacobi reported a case of Sarcoma of the Skin in a Newly-born Infant, and read a paper on the origin of such growths.

Dr. F. Gordon Morrill reported an analysis of one hundred cases of Frank Pneumonia, that term being used rather than lobar pneumonia because of the confusion caused by the use of the latter term when applied to the pneumonias of children.

Dr. Floyd M. Crandall read a paper on Hereditary Tendency in Pediatric Practice, and called particular attention to certain misapprehensions which sometimes arise regarding that subject.

Dr. B. K. Ratchford read a paper on the Symptoms of Lithemia as they appear in Children, and considered the special symptoms in detail.

In a paper on Retro-esophageal Abscess, Dr. J. P. Crozer Griffith called particular attention to the great difficulties experienced in making a diagnosis of that condition.

Dr. C. Kerley reported a case of Exophthalmic Goitre apparently cured by the use of thyroid extract. The case was an undoubted one, and the beneficial effects of the extract seemed to be equally clear.

Dr. Henry Koplik reported the extensive Use of Thyroid Extract, for the purpose of testing its value in different diseases of the blood and bones, and his conclusions suggested its more general use in those diseases.

Dr. Francis Huber also presented a paper reporting a Cure of Goitre by Thyroid Extract.

The report of the Committee on the Collective Investigation of the Antitoxin Treatment of Laryngeal Diphtheria in Private Practice was read by the Chairman, Dr. W. P. Northrup.¹

Dr. Joseph O'Dwyer read an important paper on Retained Intubation Tubes, this term being used to mean the necessity of continuing intubation long after the disappearance of the original disease.

Dr. T. M. Rotch reported cases of Diphtheria of the Eye, and discussed the subject of Antitoxin in Diphtheria.

Dr. Henry Koplik exhibited an apparatus by which the Bacteriological Diagnosis of Diphtheria could be made within three or four hours.

Dr. Edward P. Davis presented an important contribution on Pre-natal Infection in Infancy causing diseases which develop during the first month of life.

Dr. Irving M. Snow reported a case in which Poisoning by Acetanilide had resulted from the absorption of that drug in the umbilical wound.

Dr. T. M. Rotch presented a specimen of Ileo-Colitis.

Dr. R. G. Freeman presented an Improved Nursing-Bottle.

Papers were read by title by Drs. J. Lewis Smith, W. F. Lockwood, W. P. Northrup, R. G. Freeman, H. D. Chapin, Francis Huber, C. G. Jennings and C. P. Putnam.

The following officers were elected for the ensuing year: President, Dr. L. Emmett Holt; First Vice-President, Dr. Henry Koplik; Second Vice-President, Dr. Charles G. Jennings; Secretary, Dr. Samuel S. Adams; Recorder, Dr. Floyd M. Crandall; Treasurer, Dr. F. A. Packard; Member of Council, Dr. Charles P. Putnam.

The following were elected members: Dr. J. H. McCallom, Boston; Dr. J. P. West, Bellaire; Dr. Churchill, Chicago; Dr. E. E. Graham, Philadelphia; Dr. Harold Williams, Boston.

The subject of Infantile Scorbutus was selected for collective investigation, the report to be made at the next meeting. The following Committee was appointed: Drs. W. D. Booker, J. P. Crozer Griffith, C. G. Jennings, A. Caillé, J. Lovett Morse.

Cincinnati was named as the next place of meeting, the exact date of the meeting not being decided.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MAY 13, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE FOURTH CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

THE Fourth Triennial Congress of American Physicians and Surgeons, held at Washington last week, brought together between four and five hundred of the foremost men interested in the various departments of medical science and practice from different parts of the United States and Canada. It was certainly a notable gathering. Fourteen different societies and associations met again at the same time and place. The mornings were devoted to the work of the separate associations, the afternoons and evenings to the addresses, the discussions, and the social receptions of the Congress of all these associations.

The programmes presented a vast amount of promising and interesting material, and the promise and interest were fully realized. The meetings of the Congress and of the associations were well on a level with the standard set by previous occasions. On the other hand, it was again made apparent that six days' work cannot be crowded into three, and that the possible or profitable receptivity of the human mind, even when at its best, is limited. The conception of these Congresses was a good one, they have been of service to the profession and to humanity, and may continue to be; but the feeling is undoubtedly growing among those who attend them that a less proportion of the three days should be given to papers and discussions in congress and more time to the work of the societies, that the programme of the general congress should be less ambitious in order that the work in the associations may be less hurried, more thorough and more fruitful. It is not necessary to sacrifice the organization and unity of the Congress in order to preserve the continued annual satisfaction and efficient activity of the associations; but these last should be preserved.

A proposal previously submitted that the Congress be allowed to meet elsewhere than in Washington was tabled without opportunity for discussion. Perhaps

this was wise, but to be assured of wisdom it is always gratifying to hear both sides of a question.

On the afternoon of the second day a statue of the late Dr. Samuel D. Gross, erected by the American Surgical Association and the Alumni Association of the Jefferson Medical College, was presented to the United States Government. Dr. Mastin, of Mobile, presented the statue, which was received on behalf of the Government by Surgeon-General Sternberg of the Army. Dr. W. W. Keen, of Philadelphia, delivered an excellent address.

In the evening of the second day, Dr. W. H. Welch, President of the Congress, gave an address on "Adaptation in Pathological Processes."

In opening his address, Dr. Welch described adaptive processes as those causing some sort of adjustment to changed conditions due to injury or disease. Physiological adaptation is a familiar and striking phenomenon full of purpose. In the existing order of Nature, the mechanical theory is our only working hypothesis in biology. Physiological adaptation by organic evolution gives the key to the study of pathology.

Compensatory and adaptive manifestations result from energy acting upon living matter. The final result does not influence the chain of events. A mechanical explanation of the process must be sought.

Pathological adaptations have their foundation in physiological processes, but the former are markedly imperfect. They are divided into the compensatory hypertrophies, the regenerations and the protective processes. Among the first work-hypertrophies, as illustrated by cardiac hypertrophies, are especially important. Such result from changes in the individual cell, not from increased supply of blood or lymph. Cell properties determining the character of the pathological process are original physiological properties.

Applying these conclusions to the study of inflammation, we find that this is an adaptive pathological process without especial fitness justifying extravagant claims recently advanced for it. In general, the healing power of Nature is often overestimated. In the light of modern knowledge, there is ample scope for the intervention of the physician and surgeon.

Thus far the Congress, as a body, has been judiciously guided, and has kept itself clear of all politics — whether medical politics, international, national, state or civic politics; and it is to be hoped that such abstention will continue to mark its course. The social side of this meeting was somewhat more developed than has previously been the case; wives and daughters of members were more in evidence. Instead of a reception by the President of the United States at the White House, there was a reception by the President of the Congress, supported by a number of ladies, wives of officials of the Congress. At the usual banquet, which occupied one evening and was largely attended, the speeches were devoted to inculcating the importance of the Congress.

The weather was cool and rainy until the last day, which was all that could be asked of May or even of June, the month which is credited by poets if not by weather bureaus with the fairest of days; the contrast was an agreeable one in comparison with the warm receptions extended to some previous meetings.

Two of the prominent hotels, by a brutal disregard of written promises, earned the future distrust of many whom they betrayed; apart from this, most of the members will doubtless revert to this last Congress as a pleasant and profitable occasion.

A COLLECTIVE INVESTIGATION OF THE ANTITOXIN TREATMENT OF LARYNGEAL DIPHTHERIA IN PRIVATE PRACTICE.

NEARLY a year ago (July 2, 1896) a first report of the American Pediatric Society on the results of a collective investigation into the use of antitoxin in the treatment of diphtheria in private practice was published. In this issue of the JOURNAL (p. 462), our readers will find a second report of the same Society on the results of a collective investigation into the use of the antitoxin treatment of laryngeal diphtheria in private practice. To those who are interested in this subject, as all should be and doubtless are, it is sufficient to indicate that such a contribution is accessible to have it read. The process of the investigation, the results, and the recommendations deduced therefrom are set forth so clearly and succinctly that he who runs may read, and having read may comprehend.

It is sufficient to say here that sixty thousand circulars were distributed by the Committee of the Society throughout the United States and Canada with the result of securing for study 1,704 acceptable cases of laryngeal diphtheria in which antitoxin was used. Of this total nearly 61 per cent. were not operated upon, and give a mortality of 17.18 per cent., a result which, though good, the Committee rightly believes can and ought to be improved upon. Of the cases operated upon the mortality was 27.24 per cent.

The mortality in both classes of cases it is believed might be reduced, were the standard of the antitoxic serum assured, and were both physicians and friends of patients less timid in its use.

In regard to the recommendations of the Committee it is only necessary to add that they are judicious and to the point.

THE QUALIFICATIONS FOR TRUSTEES OF HOSPITALS AND OTHER PUBLIC CHARITABLE INSTITUTIONS.

THE appointment of trustees to whom is confided the administration of large public institutions is at all times attended by grave responsibilities on the part of the official charged with this duty.

When these appointments relate to charitable institutions — whether hospitals, insane asylums, reformatories or almshouses — such responsibilities are, if possible, increased, and must be a source of deep concern to the executive. Such reflections naturally lead to a consideration of the qualifications which stamp individual citizens as fit to hold these places of trust, and here we immediately encounter the inherent difficulties of the problem. Those who are most fit are often the least able or the least willing to serve. They must be sought out and not seldom importuned. He who is already laboring eight hours in the vineyard, must often be persuaded to disregard this now usual limit to civic toil and be induced to labor nine or ten, and this not for himself but for the good name of his town or city or State and for the good of his fellow-men.

There is little doubt that the highest class of work rendered a municipality is done by its unpaid Boards and Commissions. This principle in social economics is now being recognized by those interested in civic government.

Trustees of such institutions as we have in mind should be persons, whether men or women, ripe in years, of experience of human nature and of affairs, of proven probity, standing high among their fellow-citizens, without disabling political entanglements, who will take an active interest in the affairs of the institution over which they may be called upon to preside and will see to it with an eye single that such institutions are administered for the welfare of all concerned.

Such ideal citizens must be sought and may be hard to find. On the other hand, it may be affirmed that those who seek these places of trust, are very rarely if ever those to whom they should be given, and it is absolutely certain that previous political services are not qualifications.

MEDICAL NOTES.

CHICAGO COLLEGES OF MEDICINE. — There are nineteen colleges of medicine in Chicago.

THE OLDEST PRESCRIPTION. — "The oldest medical recipe," according to a daily paper, is "said by a French medical journal to be that of a hair tonic for an Egyptian queen. It is dated 400 B. C., and directs that dogs' paws and asses' hoofs be boiled with dates in oil."

INTERNATIONAL CONGRESS OF FORENSIC MEDICINE. — In connection with the Exposition at Brussels the local society announces an International Medico-legal Congress to meet August 2d to 7th to discuss the following questions: "Internal Factors in the Putrefaction of Cadavers," "The Medico-legal Expert in cases of Accidents caused by the "Ingestion of Food," "Toxicology of Acetylene," "Intoxication with Carbonic Acid," "The Criminal Insane," "Medical Professional Secrecy before the Law," "Pulmonary Docimasia," "Medico-legal Significance of Subserous Ecchymoses," "Responsibility, especially Partial Responsibility," "Hypnotism in Relation to Criminality." For further particulars address Dr. Dewez, Mons, Belgium.

THE VALUE OF A KNOWLEDGE OF NEUROLOGY. — The following dialogue illustrates the possible value of neurology from a commercial standpoint:

Materfamilias. — James writes me that he is afraid he won't get his M.D. this year; he can't do anything with neurology.

Paterfamilias. — Tell him to keep a stiff upper lip and pull it through somehow. I think I can find an opening for him as expert for the Necropoietic Railroad Corporation.

THE NUMBER OF BREWERIES. — According to a statement in the *Medical Record*, there are in the en-

tire world 51,000 breweries. Germany heads the list with 26,240; next comes England with 12,874; then the United States with 2,300; Austria has 1,942 breweries; Belgium, 1,270; and France, 1,044. In proportion to size and population, the number in the United States is surprisingly small as compared with Germany and England.

A PREJUDICED STATEMENT.—The following letter addressed to a State official, illustrates the singular prejudice which exists among the illiterate portion of the community in regard to hospital treatment:

Sir i had a son — and family livin in — and he was taken sick with Amonia, and he was taken to Hospittall and bout 12th day he was better in 2 or 3 days he grne woss probal cot A cold by not takin care of as he or to ben he did not live only or bout week — and if you will go to hospittall and look it up if thare anny chance to git anny recompence or anny law i should like to use it i dont want to have my folks go to hospittle and dye for want of not taken care of if he ben token care of and hadent got cold he ben livin now you find one that had care of him by goin thare or you go to his house and se his family you pleas rite me if anny chance i will improve it rite soon.

Ps He had what cold by catchin cold relaps of Amonia.

BOSTON.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, May 12, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 78, scarlet fever 70, measles 180, typhoid fever 5, small-pox 4.

SMALL-POX IN BOSTON.—Since the discovery and removal to hospital of three cases of small-pox in Boston last week one new case has been reported, and the three cases are all doing well. The original case from which these now under treatment arose occurred about two months ago in a car cleaner, who was employed in cleaning sleeping and parlor cars. The disease was of a very mild form, was diagnosed as chicken-pox, and the man was back at his work in two or three days. Several other cases of supposed chicken-pox developed in connection with the first case, until last week a typical case of small-pox developed in a car cleaner employed on the same railroad as the first patient, and later in two others who were relatives. Every precaution against the spread of the disease has been taken, and no further trouble is apprehended.

NEW YORK.

REAPPOINTMENT OF MR. CHARLES G. WILSON.—Mayor Strong has reappointed Mr. Charles G. Wilson President of the Board of Health, his term of office having expired May 1st. If the Governor signs the Greater New York charter his new term will end January 1, 1898.

A MEDICAL BOARD FOR THE DEPARTMENT OF CORRECTION.—A medical board for the Department of Correction was organized on April 26th, with Dr. J. P. Tuttle as President, and Dr. P. R. Bolton, Secretary. The board will have the medical care of the

prisoners in the City Prison, Penitentiary and Work-house.

DEATH OF DR. STRUBEL.—Dr. H. McDonald Strubel, a prominent practitioner of Middletown, N. Y., died suddenly at his residence in that place on April 30th. He was born at Newton, N. Y., in 1852, and was graduated from the Medical Department of the University of Pennsylvania in 1875. He was especially well known as a surgeon.

SMALL-POX IN BROOKLYN.—A case of small-pox has been reported in Brooklyn, the first in that city for two years. The patient is a working-man, who contracted the disease in New York. In the latter city, up to April 29th there had been reported since March 1st thirty-five cases of small-pox in all, eleven of which occurred at the institutions on Randall's Island.

COMMENCEMENT OF THE MEDICAL DEPARTMENT OF NEW YORK UNIVERSITY.—The fifty-sixth annual commencement of the Medical Department of the University of the City of New York was held at the Carnegie Music Hall on May 4th. There were 102 graduates, and the Faculty of Bellevue Hospital Medical College occupied seats on the stage with the University Medical School professors.

RESIGNATION OF DR. CHARLES F. CHANDLER.—Dr. Charles F. Chandler has resigned the position of Professor of Chemistry in the College of Physicians and Surgeons, which he has held for the past twenty-five years, and on May 6th, when he delivered his last lecture in that capacity, he was presented by the students with a handsome loving-cup appropriately engraved.

DEATH OF DR. CORNELIUS OLCOTT.—Dr. Cornelius Olcott, a well-known physician of Brooklyn, died at his residence in that city on May 3d, from the effects of an attack of influenza. He was sixty-nine years of age, and had been a practising physician for forty-eight years. During the late war he served with distinction in the medical service of the Army of the Potomac under McClellan and Burnside. He leaves a widow and one son, Dr. Charles Olcott, of Brooklyn.

DAMAGES WANTED FOR "SPOILED BEAUTY."—Mrs. Barbara George is the plaintiff in a novel suit brought in the Supreme Court, Brooklyn, against the Cypress Hills Cemetery Company. She asks \$10,000 damages for "the spoiling of her beauty." In June, 1895, she states that she visited her husband's grave at Cypress Hills, and found weeds growing thereon. She pulled them out, and afterwards discovered, to her cost, that they were poison ivy. In consequence of the effects of the poisoning she was confined to the house for eighteen months, and when she was finally able to go out her beautiful complexion was ruined. As she had paid a certain sum each month to the managers of the cemetery for the care of her husband's grave, she claims that the company is re-

sponsible for her condition, and so prays the court to award her the sum mentioned for her suffering and loss.

Miscellany.

THE MATERIAL RELICS OF THE GREAT.

THE recent instances of the cremation of distinguished medical men has caused some discussion as to what is the most reverent way of treating "remains." Mummification is out of the question, for a mummy is almost as repulsive as a corpse mouldering in an ordinary coffin. It is this that makes many men prefer the prospect of cremation, with possible preservation of part of their ashes. A singular idea struck the rulers of France during the Great Revolution. In 1793, under the influence of a fanaticism yet more terrible to the living, the Convention ordered the destruction of the bones of the kings of France in the royal vault of St. Denis. This act of desecration is specially odious to the anthropologist. How interesting it would have been to examine carefully the cranium and skeleton of Dagobert, who died in the seventh century! His remains were ruthlessly scattered over the street. A very different step taken by the Convention has been till recently forgotten. The bodies of several great men were exhumed and taken to the national mint to be made into a phosphatic glass. Cups were then to be moulded out of this material, so that citizens could drink toasts in gratitude to the great dead out of their very remains! As usual, the order was revoked very soon, and moderate republicans re-interred what red republicans had exhumed. D'Arcet, who was charged with attempting the vitrification of the bones, retained the lower jaw of Molière; some bones of La Fontaine were also preserved. The systematic preservation of integral parts of the skeleton would, however, be displeasing to the public mind, and would seem almost as ghastly as Isabella's pot of basil.

THE OUT-PATIENT ROOM AS A FIELD FOR RESEARCH.

THE failure to properly utilize the opportunities for clinical study which are afforded by out-patient departments is so general, that the following remarks of a correspondent of the *British Medical Journal* on this subject are of interest:

How great a field for clinical research lies open and unused in out-patient rooms is a matter for reflection. It is not wonderful, for in this department the time is short and the work heavy, and the patients' attendances or non-attendances are due to so many causes remote from the progress of the disease for which they are under treatment that it has seemed to many useless to try to obtain valuable generalizations from incomplete particulars. Definite results are hardly to be hoped for, and individual experience is reduced to its minimum value for want of systematic recorded observation of the cases and their treatment. The recorded observations of any one man extending over a number of cases and a year or two of time are of value; how much more would this be true of a scheme of concerted action, followed concurrently by investigators in one or in several hospitals. One great gain would be that a man wishing to compare his conclusions with those of others would probably have at his disposal data less inade-

quate and makeshift than they too often are at present, and would probably less often be obliged to support first-hand theories by second- or third-hand facts, or with facts the scarcity of which is as often as not the measure of their aptness. No very elaborate changes would be necessary in order to turn waste material to good use. A few short, printed lists of questions or observations concerning the diseases for the time being under study, with dates and results of treatment shortly noted, would probably suffice to place a quantity of excellent material in the hands of those disposed to put it to scientific use. A little order, and a few intelligent assistants supervised by a registrar, all of whom might be obtained to their own great advantage among medical students or newly-qualified men, would under capable direction serve to set going and maintain a most valuable system of investigation. Climate or season, material conditions, heredity, susceptibility and idiosyncrasy are among the various influences and conditions which might be made, even in a fluctuating out-patient practice, to yield information of inestimable value.

The above reflections have been suggested by a study of an experimental analysis of a year's out-patient letters in one department of a children's hospital. The notes were taken with no particular aim in view, and yet as they stood they recorded much, and might easily have recorded more. They indicated various seasonal variations in disease; for instance, a marked group was formed by rheumatisms of every variety, including cases of morbus cordis and chorea, of which nearly all presented themselves for treatment during the summer. Diarrhea, of course, emphasized itself as a summer malady, while anemia showed a marked preference for the spring months. Marasmic and wasting diseases in children, even among those said to be entirely breast-fed and not ostensibly due to specific diseases, stood significantly highest in the month of August. In cases of pleurisy in an early stage, but at times accompanied by effusion, very satisfactory results were noted from the administration of salicylate of soda in fair doses. In cases of whooping-cough, in which the paroxysms of coughing were severe and the bronchitis only moderate, the benefit of antipyrin was markedly shown. The drug treatment of broncho-pneumonia did not yield any definite results, but in cases in which a treatment consisting of very hot baths and plenty of fresh air out of doors was carried out, surprisingly good results were noted. These conclusions, drawn from a brief inspection of imperfect material, are not, of course, particularly new or valuable, but the point is that while so much is being said of the difficulty of finding clinical material, either for teaching or other purposes, they suggest a neglect of existing material which is both blameworthy and unaccountable.

Obituary.

JOSEPH W. CUSHING, M.D.

DR. JOSEPH W. CUSHING, formerly of Boston, died at Brookline, May 9, 1897, at the age of sixty.

Dr. Cushing was of a very retiring disposition, but this did not prevent his being known to many of his professional brothers as a man deeply interested in medicine, industrious in reading, intelligent and devoted in practice. He had been for many years a councillor of the Suffolk District Society, and was an original member of the Brookline Medical Club.

After having been house-surgeon of the Massachusetts General Hospital, he studied abroad, and then entered the army as assistant-surgeon, being employed during most of his military service at the Lovell General Hospital. After the close of the war he entered general practice at the South End of Boston, where he remained during most of his professional career, and where he had a large practice. His wife, the daughter of the late Charles Woodbury, and two of his three children survive him.

METEOROLOGICAL RECORD

For the week ending May 1st, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 3,149; under five years of age 1,052; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, diarrheal diseases and fever) 382, acute lung diseases 529, consumption 401, diphtheria and croup 120, diarrheal diseases 62, scarlet fever 45, typhoid fever 42, cerebro-spinal meningitis 39, whooping-cough 33, measles 22, erysipelas 11, small-pox 5, malarial fever 3.

From typhoid fever Philadelphia 18, Pittsburgh 5, Chicago and Baltimore 4 each, Cincinnati 3, New York and Boston 2 each, Brooklyn, Cleveland and Nashville 1 each. From cerebro-spinal meningitis Boston 15, New York 11, Somerville, Philadelphia, Lowell, Salem and Chelsea 1 each. From whooping-cough New York 11, Chicago 7, Brooklyn 5, Philadelphia 4, Pittsburg 2, St. Louis, Boston, Cincinnati and Somerville 1 each. From measles New York and Brooklyn 5 each, Baltimore 4,

Chicago 3, Philadelphia, St. Louis, Cincinnati, Pittsburg and New Bedford 1 each. From small-pox New York 4, St. Louis 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,992,524, for the week ending April 24th, the death-rate was . . . Deaths reported 3,965; acute diseases of the respiratory organs (London) 289, whooping-cough 109, measles 101, diphtheria 57, diarrheal 40, scarlet fever 31, fever 29.

The death-rates ranged from 10.1 in Derby to 36.1 in Bolton; Birmingham 19.2, Bradford 18.5, Cardiff 17.2, Gateshead 11.3, Halifax 19.1, Hull 15.3, Leicester 17.9, Liverpool 24.7, London 17.5, Manchester 28.8, Newcastle-on-Tyne 17.0, Nottingham 18.6, Portsmouth 13.1, Sheffield 18.8, Sunderland 26.1.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 1, 1897, TO MAY 7, 1897.

The following named officers are detailed to represent the Medical Department of the Army at the seventh annual meeting of the Association of Military Surgeons of the United States, to meet at Columbus, O., May 25 to 27, 1897: LIEUT.-COL. WILLIAM E. WATERS, deputy surgeon-general; MAJOR HENRY LIPPINCOTT, surgeon; CAPTAIN ROBERT J. GIBSON, assistant surgeon.

FIRST-LIEUT. GEORGE A. SKINNER, assistant surgeon, will proceed to Fort Spokane, Wash., and report for temporary duty during the absence of CAPTAIN EDWARD R. MORRIS, assistant surgeon, on leave for six months, to take effect on or about May 18, 1897.

By direction of the President, the retirement from active service this date, May 3, 1897, by operation of law, of COLONEL CHARLES T. ALEXANDER, assistant surgeon-general, U. S. A., is announced.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE FIFTEEN DAYS ENDING APRIL 30, 1897.

ROSENAU, M. J., passed assistant surgeon. Granted leave of absence for three days. April 21, 1897.

SOCIETY NOTICE.

SUFFOLK DISTRICT MEDICAL SOCIETY.—The Section for Clinical Medicine, Pathology and Hygiene will hold its regular meeting on Wednesday, May 19th, at 8 p. m., at the Medical Library, 19 Boylston Place.

At 8 to 8.30. Short communications by Drs. Cones, Capps and Taylor.

At 8.30. Dr. G. Liebmann: "Experience with Hyperacidity of the Stomach."

E. W. TAYLOR, M.D., Secretary.

ERRATUM.

On page 430, line 31 of the number of the JOURNAL for May 6th, October 26th should be October 16th.

RECENT DEATHS.

JOSEPH WHITNEY CUSHING, M.D., M.M.S.S., died in Brookline, May 9, 1897, aged sixty years.

GEORGE WASHINGTON BURDETT, M.D., M.M.S.S., died in Clinton, May 10, 1897, aged seventy-eight years.

WILLIAM BAXTER CUSHMAN, M.D., M.M.S.S., died in Oxford, February 25, 1897, aged forty years.

DR. JAMES P. WALKER, died in Manchester, N. H., on May 6th, aged sixty-nine years. He was graduated at Harvard Medical College in 1856. He had practised in Manchester continuously since his graduation. He was assistant surgeon nearly a year on the medical staff of the Fourth New Hampshire Volunteers and had served a number of years on the Board of Education and in the Legislature. He was a member of the Harvard Alumni Association.

VAGINAL MYOMECTOMY.¹

BY EDWARD L. TWOMBLY, M.D.,

Gynecologist to St. Elizabeth's Hospital, Out-Patient Department.

Mrs. D., married, forty years old, born in Nova Scotia, and living in Braintree, Mass., entered St. Elizabeth's Hospital, August 15, 1896, with the following history: father and mother died of old age. Family history good. She was married at sixteen years. Has three children, youngest eight years old. One miscarriage. Menstruation began at thirteen years and was always regular, without pain, flowing three or four days, until last May. Personal health always good.

May 8th. Menstruation began, and lasted three days. It returned on May 15th, and she has flowed intermittently ever since, only stopping for a few days at a time. Blood thick, black, sometimes offensive. No pain. Has become pale and weak.

Examination showed an enlarged uterus, a hardness of posterior wall, but no irregular masses without. Diagnosis of myoma of uterus; but whether interstitial or submucous was to be determined at time of operation. It was suggested that the cervix be dilated on the day before operation for purpose of further diagnosis and, if possible, remove the tumor by vagina. If it were then found inexpedient to do it, a laparotomy could be done, and she was prepared for it.

About 4 P. M. the largest size tupelo tent (22 English) was inserted without ether after dilatation with Hanks' dilators up to the highest number. Iodoform gauze packed about to keep it in place. The tent gave the patient very little pain, and was not removed till the operation on the next morning. All cleanliness and aseptic precautions were observed. Vagina cleansed with permanganate and oxalic acid and corrosive. The finger entering the uterus easily made out a submucous fibroid on the posterior wall of it, and could determine its upper portion. It seemed a very suitable case for the vaginal operation, and that was done.

The cervix was divided posteriorly in its central axis for its whole length by the scissors, and each part was grasped by a pair of bullet forceps. Very little bleeding followed. This gave room enough to pass a knife, on the finger as a guide, nearly to the top of the tumor, and the incision was made down through the mucous membrane from top to bottom. With fingers and scissors the myoma was nearly enucleated, and then grasped in vulsellum forceps and twisted out. No hemorrhage followed, so the interior of the uterus and the remains of the tumor's sheath were carefully curetted. Some clots and hyperplastic tissue removed. The cervix was then reunited with silkworm-gut sutures and a strip of gauze placed in the cervical canal as a wick-drain for any bleeding. Patient put back to bed in good condition.

There was very little pain afterwards, no bleeding. The gauze was removed on the fourth day, no temperature. On the tenth day she was sitting up in bed, and she went home three days after. She need not have been kept in bed so long except that she was very weak and tired out from the loss of blood previous to entering the hospital.

Examination, six months afterwards, showed nothing

abnormal, no development of another myoma-bud in the same or different locality, a small uterus, menstruation regular but occurring every three and one-half weeks, no pain, flowing slightly for two days instead of four, cervix perfectly united, woman in good health (with cachexia gone) and doing her household work in good spirits.

This case illustrates the subject which I wish to bring before you. While so many hysterectomies are being done in these last three years, we are apt to lose sight of other and simpler operations. That every fibroid of the uterus should be removed by hysterectomy is too sweeping a statement, and yet there are men who uphold it.

That there are many indications when a hysterectomy ought to be done, I do not doubt and often would advise; but I wish to leave out that important operation in this discussion and come at once to the question, whether the lesser operation of vaginal myomectomy has not still its place in the treatment of this disease. Another point I wish to emphasize is that an earlier diagnosis by the general practitioner will be of great importance to the patient, and lessen the necessity of a major operation in many instances.

It is perfectly justifiable for the general practitioner to insist on a vaginal examination in a married woman, when any irregularities of menstruation occur, or where unaccountable pain is present. By so doing he may be able to diagnose the myoma before it has grown to so great a size that the proposed operation is impracticable, and save the woman much suffering, and perhaps the loss of her uterus.

We know that fibroids of the uterus are divided into three general classes: (1) The subserous, (2) the interstitial or intramural, (3) the submucous.

As a purely fibroid growth it is exceedingly rare, for with few exceptions, the tumor contains muscle-cells. These growths of the uterus should more properly be called myomata, myo-fibromata, or best of all, fibro-myomata. In the later studies by Rösger and Kleinwächter, the theory is confirmed that myomata are originally developed from the muscular coat of the uterine arteries. "The embryonic cells of the united Müller's duct are the common origin of the walls of the uterine vessels and of the muscle-cells of the uterine walls."

Senn says that in the majority of cases, the tumor springs from a matrix of myoblasts in the uterine tissue, and in exceptional cases, it may start from a similar matrix in the wall of the blood-vessels.

Virchow also confirms this idea by attributing the new growth to a hyperplasia of existing muscular fibres.

The growth is in the direction of least resistance, and it pushes before it the mucous membrane or peritoneum, which with the blood-vessels that supply the tumor form the pedicle, when there is any. The more fibrous the tumor the less abundant is the blood-supply, and as the muscular elements predominate in the uterus, we are more apt to get a vascular tumor within. When the tumor is born (so to speak) from the uterus, other sources of nourishment may occur which increase its vascularity, or, when cut off by twisting or pressure, diminish it.

These tumors degenerate frequently because of interstitial pressure or thrombosis producing edema. They are liable to become cystic, hyaline, more often fatty or calcified, or transformed into sarcomata if situated in the body of the uterus. The transforma-

¹ Read before the Obstetrical Section of the Suffolk District Medical Society, January 27, 1897.

tion of intra-uterine myomata into carcinoma has never been demonstrated.

The exciting cause is some disturbance of menstruation which gives rise to tissue-proliferation.

Frequency. I have been amazed at statistics in looking up this subject to find its relative frequency.

Pozzi says that one-fifth of all women who arrive at the age of thirty-five, are so afflicted. (He considers that there is seldom a single fibroid, but usually more than one.) Klob states that 40 per cent. of the uteri of females who die after the fiftieth year, contain fibroid tumors.

In 528 cases, tabulated from different operators, 18 per cent. were in women between twenty and thirty years of age; and one-third of the whole number occurred in women before the age of thirty-five, and one-fourth of the whole number had symptoms before the age of thirty. The majority of cases occurred between the ages of thirty-five and forty.

Senn says that marriage increases the frequency, and that in 33 per cent. of the married women the tumors caused sterility.

Hofmeier studied 213 cases and their influence upon conception, and concluded that they had no effect upon fertility or sterility. Another set of statistics shows that these tumors occur in the unmarried 25 per cent., married 75 per cent., and that 30 per cent. of the married were sterile, but that the tumor had no influence on the sterility.

Location.—Subserous 25 per cent., intramural 65 per cent., submucous 10 per cent. They may start from any portion of the uterine wall, and near the cervix is given as the most frequent location, and the next favorite position is the posterior wall below the fundus. Mundé in 130 cases of fibroids at Mt. Sinai Hospital found only three in the tissue of the cervix. Twenty-one had developed into polypi. The great majority were in the body of the uterus.

I would call your attention also to the results of study regarding the conditions of the tubes given by Fabricius, of Vienna. In 42 cases, he found them normal in 17; unilateral catarrh in two; and all forms of bilateral tubal disease in 23; which shows (in these cases certainly) either that the tubes are more frequently affected than not, or else that they were long-standing cases and that an early diagnosis might have prevented this complication. He adds, however, that along with the smallest tumors, were the greatest alterations in the tubes.

The *Symptoms* are too often overlooked because of the insidious and generally slow growth, and the pains and aches are attributed to displacements. We should therefore be more careful in making our diagnoses; for, as I hope to show, the earlier we can make them, the better it is for our patients (although not for our pocket-books), and the tumors admit of easier removal.

The tumor of itself may not give rise to any symptoms for a long time—one small nodule or several small nodules on the surface of the uterus under the peritoneum do not disturb or cause any trouble. It is only when they grow rapidly.

On the other hand, intramural tumors of small size pressing towards the mucosa may give rise to decidedly nervous symptoms from pressure. "The degree of suffering is not dependent upon its size." The first symptom generally noted is some change in menstruation, and, at its beginning, the usual symptoms are aggravated. Profuse menstruation is a most impor-

tant factor. The duration of the period is prolonged. Then follow irregularities and hemorrhages between times. Uterus is painful on pressure. The menorrhagia varies in intensity from time to time. The cervix becomes soft and dilatable and there are copious catarrhal discharges. There is apt to be irritability of the bladder and rectum and pain in the pelvis when the tumor is large enough to press on the crural vessels and nerves.

The *Diagnosis* can be made from these foregoing symptoms, in connection with the necessary physical examination, which should show an increased localized resistance of the uterus over the tumor if the tumor itself cannot be felt. The uterine sound reveals much, and should be used if pregnancy can be safely excluded. Retroflexions, pelvic peritonites, ovarian tumors, and malignant tumors can be generally differentiated. Pregnancy is the most difficult thing to exclude, and many mistakes have been made. Many an operator has closed the abdomen over a pregnant uterus, which had previously been diagnosed as a fibroid. The breasts and cervix simulate the changes of early pregnancy, but in pregnancy the lower segment of the uterus presents a characteristic bluish-red color, and both uterine arteries are enlarged, which are not so to the same degree in myoma. I believe that it is wise to give ether for thorough examination in doubtful cases.

The *Prognosis* is now considered more grave than was formerly supposed, ten years ago. It is estimated that 10 per cent. of all cases die, and that hemorrhage and uremia are the most frequent causes. (A myoma, stationary as regards growth for a considerable length of time, grows very rapidly during pregnancy, but it may as rapidly diminish during involution. Unless the myoma is very large, pregnancy is apt to be completed without abortion. In 119 cases, 21 aborted, and 98 were delivered at full term.)

I have thus passed rapidly in review these main points collected from all reliable sources in order to refresh your memory, and because they have an important bearing on the method of treatment which I especially wish to bring to your notice. Ten years ago, aseptic surgery was but just beginning and all statistics of operations before that time are of but little value now. Asepsis has brought about a revolution of methods. Old methods of doubtful utility are now rendered safe procedures. Opening the peritoneal cavity either through the abdomen or vagina under aseptic precautions is without danger. No wonder, then, that in the last three years hysterectomy for fibroids has attained great proportions and a low mortality. It has its place, and a very important one; but while that truth remains, it is also true that many hysterectomies are done needlessly for small tumors of this kind.

A very decided opinion is given by Emmet who says, "No one should remove the uterus until the uterine canal had been dilated, and digital exploration had enabled him to form an intelligent opinion of the true position and condition of the tumor." I suggest that vaginal myomectomy has a place in surgery still, and should more often be performed.

Martin, Polk, Price, Gordon and Homans prefer hysterectomy, Obalinsky, Von Erlach, Péan, Mundé, Kelly of Baltimore, T. A. Emmet and Thomas are against it.

Most operators have limited this operation to tu-

mors "not larger than a fetal head." That seems, and is, a severe limit, for in great efforts to remove such large masses, by cutting or otherwise, there is much fraying and bruising, and sloughing is the result. All such processes are to be avoided as far as possible.

I would limit the operation to interstitial or submucous fibroids of moderate size where the base of the tumor can be reached, or where there is a fair possibility of enucleation without great tearing of the tissues.

I will not speak of medical treatment, which is palliative only; nor of electrolysis, which has given no favorable results in the hands of most men.

Under aseptic surgery, the vaginal operation is the ideal one, because there is less mutilation of the patient (depriving of uterus or adnexa); no abdominal wound; slight, if any, mortality; and it is not very difficult to do. Ten years ago, such operations were done, and some deaths occurred. Skene had 100 cases and one death. Mundé had 130 cases and three deaths.

Mundé says that he would not operate simply because it was a fibroid, but only when it produced serious symptoms, such as hemorrhage, pain, rapid growth causing injurious pressure; when it is associated with inflammatory diseases or pus-tubes; or when the woman is scared enough to be invalidated by the thought. I believe that rapid growth or hemorrhage demands this operation and should consider the advisability as soon as a diagnosis was made, before such occurrences. The danger of hemorrhage and of the operation increases with the size of the tumor.

The age of the individual is an important factor, for we know that many of these tumors atrophy or remain at a standstill after the menopause, although many others take on a new lease of life and growth. Those cases should always be kept under observation if possible.

(1) Subperitoneal myomata. In these days when we venture to open the anterior or posterior vaginal sacs with impunity, and the tumors are small nodules on the uterine surface, their capsules can be opened and the tumor shelled out. When, however, they are deeply imbedded in the uterus, the operation is more difficult and the nest left after enucleating the tumor is very apt to bleed and several deaths from hemorrhage or sepsis following have been reported. A few small nodules on the uterus may give rise to no symptoms and no harm come to the carrier by their presence. The vaginal operation in subperitoneal cases should be limited to the small, easily accessible and very superficial nodules. The vaginal vault should be closed afterwards.

(2) The Submucous variety, which have burst into the uterine cavity and become pedunculated—the fibrous polyp, so-called. I think all operators remove this growth through the vagina, the self-evident way.

In these cases, while making strong traction with vulsellum forceps well embedded, it seems to be a good plan to divide the mucous membrane covering the pedicle by a circular incision far enough away from the attached portion of the pedicle so as to allow a cuff of mucous membrane which will cover the wound afterwards. By using blunt-pointed scissors, very little hemorrhage occurs. Reflect back this cuff, and the pedicle containing the principal blood-vessels of the tumor is reduced in size, and its capsule can be pretty well exposed at the base. Then enucleate if

the pedicle is broad, twist if narrow. The tampon of iodoform gauze (long strip) is then generally used and allowed to remain for three or four days. Afterwards the mucous membrane covers the granulating surface, and the entire wound heals very rapidly within a week. If traction partially inverts the uterus, the operation is easier, but one must be careful to push back the fundus into its normal position again and look out for bleeding.

(3) Interstitial, or interstitial becoming submucous. This class of cases call for enucleation or morcellation. Péan did wonders on large growths by this latter method, attacking them from the centre after cutting into them and removing them piecemeal until all their tissues had been removed. He detaches the cervix first, as in performing a vaginal hysterectomy, but avoids opening the peritoneal cavity if possible. Thomas does enucleation whenever practicable, using his "spoon-shaped" saw by which he makes a blunt dissection close to the capsule after a long incision through the mucous membrane covering it, parallel with the long axis of the uterus.

T. A. Emmet read an interesting paper in 1895, in which he advocates traction as very important in helping to obliterate the cavity left, after removing the tumor. He says that the muscular tissue contracts very quickly and promptly even in subperitoneal tumors in this way. He uses blunt, curved scissors for enucleation after a longitudinal cut down to the capsule, and makes continuous traction, first applied at the upper portion of the tumor; for the pedicle is situated at the lowest part of the growth, near the mouth of the uterus. Sometimes he uses a cord with a slip-knot if there is much of a pedicle. The traction is not made directly downwards, but he twists the growth laterally from side to side while pushing away the shell from the tumor, so to speak, instead of digging it out. Downward traction may be made later on. His strong point is traction so as to pull up into the cavity or nest of the tumor the underlying muscular fibres which readily contract and partially obliterate it—illustrated by removing a ball from a soft mass of tar. He finally adds that if the mass becomes frayed out or in shreds in the effort of removal, "it is better to desist, wash out, and pack with gauze; and if in twelve hours there is any appearance of sloughing, remove the uterus without delay, or you may get blood-poisoning."

Now, if we can take the experiences of all these operators, and combine the important points, we may reach the best method to follow. That operation would be as follows: Not a gradual dilatation of the cervix with gauze for several days, but a rapid one the day before operation. A creolin vaginal douche one to two per cent. twice daily for two days before the operation. A rapid dilatation with Hanks' dilators up to the highest number, and the insertion of the largest tupelo tent possible, for further dilatation, under careful asepsis, on the afternoon of the day before operation. Generally the cervix is soft and dilatable, and ether will not be required. Packing about the cervix with iodoform gauze to hold the tent in position and partly fill the vagina for further protection. The tupelo must not remain in the cervix if there should be a chill, or chilly sensations accompanied by nausea and vomiting and a temperature rising above 100° F. Generally the discomfort is not great, and a little codeia or morphine can be given, if neces-

sary, for the pain. The tupelo is allowed to remain until after the vagina is thoroughly washed with soap and water, followed by permanganate and oxalic acids, and sterile salt-solution at the time of operation the next morning, when the patient is under ether. I prefer the tupelo-dilatation, as one gets a more even stretching of the canal than if rapid dilatation were practised with the uterine dilator at the time of operating.

The plug is now removed, and the aseptized finger of the operator explores the uterine cavity and determines the condition and true position of the tumor. If the finger can sweep around the growth, if it does not include the whole wall of the uterus, if, as in the majority of cases, the attachment is low down in the body of the uterus, or if the tumor is felt under the mucous membrane, interstitial, but bulging into the cavity rather than outwardly, it can be deemed advisable to proceed. If there exists a doubt that the uterus may be ruptured or a hole made into the peritoneal cavity, or by reason of a very large pedicle that much hemorrhage may be apprehended, preparations may be made for tying the uterine arteries, or a complete vaginal or abdominal hysterectomy, as the operator prefers. The cervix is then slit in the middle line posteriorly (to allow more room) up to the body, with straight seissors. The posterior division is much safer than the lateral, as the wounding of the large vessels is thus prevented. Often no bleeding follows. When it does, and any way, both lips of the divided cervix are seized by a pair of bullet forceps which holds and steadies but does not crush the tissues as clamps would. With the finger as a guide, a long-bladed knife is passed to the highest point of the tumor, and an incision is made down onto the tumor, parallel with the long axis of the uterus. The mucous membrane is pushed away from the incision on either side, the myoma seized and firmly held by vulsellum forceps, and traction made, as described by Emmet, while the dissection is made close to the capsule. Laceration of the uterine tissue must be avoided as far as possible, because it is apt to give rise to troublesome hemorrhage.

Fingers can be used most safely in this shelling-out process. The saw-spoon is also useful in many cases. It is sometimes easier to begin from above and sometimes from below. In the case reported, the shelling process was easily accomplished from below upwards. If the myoma is too large to remove entire, then it is to be done by *morcellement* (as previously described).

Finally, the myoma may be twisted out from its bed when it has been pretty well separated from its adhesions and where only a small pedicle or connection remains. If any hemorrhage follows or if the cavity remaining be large, it is advisable to pack it with iodoform gauze, the end of which protrudes from the cervix; and that is allowed to remain for three days. In other cases, a small wick-drain of gauze through the cervix is all that is required. Where it is possible, a careful curetting of the uterine cavity and the removal of shreds about the wound with the curette is allowable.

The last step is to sew up the cervix, which has been incised at the beginning of the operation, using either silkworm or chromicized catgut, and arranging the iodoform-gauze in the canal for drainage or for checking hemorrhage. Unless there has been a very great deal of morcellation, or vigorous, long-continued

traction, there is very little shock, and the after-treatment is simple. A vaginal douche of plain hot-water or corrosive (1-5,000), morning and night, after the first day, for four days; sitting up in bed on the sixth; out of bed on the eighth; home on the tenth or twelfth, for average cases.

I perform this operation with the patient on her back, for the relative position of the tumor to the uterus and surrounding parts seems to be better marked out; but other operators often use Simm's position.

From the fact of the great frequency of these growths at a comparatively early age (thirty-five years); that one-fourth of the women have some symptoms before they are thirty; that the frequency of the growths increases with the married state (75 per cent.); that they may be a cause of sterility; that an examination is perfectly allowable when there are irregularities of menstruation in married women; that about 65 per cent. are intramural, with tubes affected sooner or later (estimated in one-half the cases), and that in many cases the growth towards the place where the functional activity is greatest (that is, the uterine cavity) is apt to be single, while the multiple fibroids are crowded out towards the peritoneum; that degeneration is so common; that 10 per cent. of all cases die from hemorrhage or uremia, and that the danger of hemorrhage increases with the size of the tumor, — from all these facts, my conclusion is that I am justified in recommending an early operation in this class of cases, irrespective of severe symptoms, and this special operation because —

- (1) It causes very little mutilation.
- (2) There is slight danger from sepsis.
- (3) There is very little shock.
- (4) It is not excessively difficult to perform.
- (5) It has scarcely any mortality.
- (6) There is a rapid convalescence.

A REPORT OF A CASE OF SUPPURATING OVARIAN CYSTS. OPERATION AND TREATMENT.¹

BY D. P. RONAYNE, M.D., BOSTON,
Gynecologist to Out-Patients, Carney Hospital.

As it is rather an unusual condition to find cysts of any considerable size of both ovaries, at the present time, when the large ovarian cyst of former years is almost a matter of history, owing no doubt to the watchful eye of the gynecologist, a report of such a case may be of some interest to the members of the Society. Due to the same alertness, it is a fact that suppurating diseases in the pelvis come to operation at a much earlier period than the present case did, thereby giving to the patient added chances of recovery on account of better and more favorable conditions.

A brief history of this case is as follows: First saw Mrs. M., October 27, 1896, through the kindness of Dr. W. H. Devine, who had seen her for the first time the day before. She was twenty-eight years of age, married two and a half years, and had always enjoyed good health. Regular and painless menstrual periods and negative family history. About a year and a half ago she first noticed a swelling in the right side; this tumor gradually increased so that it was especially noticeable when patient was lying on the right side. Pain in this side and hip increased in severity as the

¹ Read before the Obstetrical Section of the Suffolk District Medical Society, January 27, 1897.

tumor enlarged, so much so, that she suffered considerable discomfort when lying down. A year ago was confined to bed by the intensity of the pain and the exhaustion from constant nausea and vomiting, she being pregnant at the time. As pregnancy advanced, the mass assumed a higher level in the abdomen; and this, together with the increasing size of the uterus, caused dyspnea.

June 28th. Confined; forceps delivery; and on the second day following had fever, preceded by a chill, abdominal distention and pain.

After a month she was able to sit up, although distention, pain, and evening temperature persisted for some time. Subacute attacks occurred at irregular intervals; during the month previous to my seeing her she had three such attacks, and was confined to bed from the last one when I first saw her. At this time she presented all the appearances of a thoroughly septic woman—facial expression, clammy skin and a weak, irregular pulse. Examination of the abdomen showed a uniform enlargement, dulness on percussion, and tenderness. Palpation gave the sensation of a solid tumor such as a fibroid, so definite and circumscribed was the peritonitis. By vagina, the uterus was found slightly enlarged, forward and to the right of the median line, fixed in that position by a mass in the left pelvis which extended posterior to the uterus. The right pelvis was free from any appreciable mass. By rectum the contents of left pelvis could be mapped out very distinctly. Two days previous there had been a discharge of a brownish, foul-smelling fluid from the rectum. Owing to the extremely exhausted condition of the patient, palliative treatment (ice-bag, douches, stimulants and saline laxative) was advised, with the hope of improving her condition.

Ten days later I saw the patient again, and found that the abdominal distention had in a great measure disappeared, leaving the walls lax. A large, fluctuating tumor could now be mapped out, occupying a median position in the abdomen and extending about three inches above the umbilicus. Pressure on the fundus of the cyst caused a discharge of thin pus from a sinus at the umbilicus which had been discharging for three or four days. Mass in left pelvis found the same as upon previous examination. As the patient's general condition was improved, operation was advised.

After the usual preparations, on November 11th, a median incision was made, and the first difficulty of opening the peritoneal cavity presented itself on account of the cyst being firmly adherent to the abdominal wall. The parietal peritoneum was thickened and friable, and any attempt to strip it back from the cyst wall proved unavailing. In the upper angle of the wound the convex surface of the cyst dipped away from the abdominal wall and thus allowed the finger to make the opening wedge, and after considerable manipulation the hand could be introduced into the cavity. The cyst was found adherent on all sides by fibrous adhesions which were separated with difficulty. During the separation the cyst wall ruptured, and the contents—a thin, dark-brownish fluid, with a fecal odor and filled with flakes of necrotic material—was discharged over the field of operation. The cyst was delivered through the incision, and the omentum was found adherent to its anterior and superior surfaces. Owing to its congested appearance and free oozing from the denuded surfaces, a large portion of it was ligated and removed.

Following down into the pelvis the cyst was found to have a broad pedicle about four inches long coming from the right side of the uterus. Tube and pedicle were ligated and excised. No twist in the pedicle could be demonstrated. The left pelvis was filled with a tumor mass, about the size of a grape-fruit, surrounded by adhesions and exudate. This proved to be a cyst of the left ovary. It ruptured during the attempt to separate the adhesions; and discharged a fluid of the same character as that of the larger cyst. The left tube, which was enlarged and thickened, as was the right, showing a chronic salpingitis, together with the cyst sac was ligated and removed. During the operation not a coil of intestine was visible. They were apparently walled off completely by adhesions and confined to a space immediately beneath the diaphragm.

The exact location of the large cyst was well defined by adhesions. It extended from the right iliac fossa across the abdomen, so that the median point of the fundus was three inches above and two inches to the left of the umbilicus. After removal of cyst there were many oozing surfaces throughout this area. The peritoneal cavity was flushed out with warm normal salt-solution, and cleansed as thoroughly as possible. Strips of iodoform gauze were placed about the stumps of the omentum and loosely packed in the space occupied by the cyst. Another strip filled the pelvis, and the loose ends were brought out at the lower angle of the wound. Through and through silk-worm-gut sutures were used to close the wound, with the exception of the lower angle, and a large gauze dressing was applied. The operation consumed an hour; and at the end the patient was in a condition bordering on collapse, so that active stimulation had to be resorted to at once. Stimulating rectal enemata and a transfusion of two quarts of salt-solution beneath the breasts and in the thighs produced beneficial results.

During the first twenty-four hours patient suffered severe shock; the pulse was weak and compressible. During the second twenty-four hours patient had recovered somewhat from the shock, and showed a slight improvement in general condition. Drainage was continued free by removing a small portion of gauze from day to day. On the fifth day all gauze was removed and irrigation with half-strength peroxide was begun, and repeated three times each day. The discharge at this time had a fecal odor, but there were no other evidences of a fistula. Sutures were removed on the eighth day, the wound having healed contrary to expectation. The general condition of the patient showed very little improvement; and on the eleventh day temperature rose two degrees, and remained at 103.5°, with the accompanying weak, thready pulse. The patient was in very poor condition, presenting all the symptoms of profound sepsis. It was at this juncture that I thought of using anti-streptococcus serum. I had seen what I thought were good results in three similar cases, when it was first proposed as a remedy. Not being able to obtain the serum at the time, it was suggested to try phenol as a substitute. This is prepared after the formula of Edson. Where the preparation had been used in cases of phthisis the results were such as would be desirable to obtain in this case, namely, a lowering and finally a disappearance of fever and regular heart action. This was probably due to a decreased absorption of septic material.

The first injection of a drachm was given on the fourteenth day, and repeated twice a day. The amount

was increased ten minims at each injection until the maximum dose was two drachms. During the first twenty-four hours the changes noted were a lowering of the temperature by 1.5° and a drop in the pulse from 150 to 130 beats. The character of the discharge changed from a thin, dark-brownish fluid to a thick, purulent one, still having a fecal odor. During the second twenty-four hours temperature remained the same, pulse dropped to 120. The third day the temperature was 100° and pulse 110. From this it will be seen that the most marked action was on the heart, the pulse becoming slower and stronger. There was a marked change in the general condition of the patient, and for the first time she seemed to be interested in things about her; color and condition of skin improved, and a large amount of nourishment was taken. On the fifth day the temperature reached normal, and patient was able to turn on side. From this on the patient improved rapidly. Injections were omitted after the ninth day, the temperature having remained normal for forty-eight hours. There was an evening temperature on the thirteenth day due, I think, to the superficial closing of the fistula. The patient was up at the end of the fourth week from operation and was discharged two weeks later. There remained a small sinus which communicated with an indurated mass on the right side two inches above the umbilicus. This was probably due to an exudate about one or more of the silk ligatures used in tying off the omentum.

Several points of interest are suggested by this case.

First, the value of some antitoxin treatment in pus case coming to operation or in those where by accident sepsis follows operation. The study of serum therapy which is now engaging the attention of scientific investigators will, I think, produce something of value for these cases. We have all seen cases of septicemia due to one or more of the less virulent of the infectious organisms where the patient after struggling along succumbs because the eliminating functions of the body were no longer able to perform the work demanded of them. If in these cases by the introduction into the circulation of some antitoxin which would change the character of the ptomaines produced and thereby allow the eliminating functions to store up some reserve energy it would tide the patient over the danger point and add to the chances of ultimate recovery. In a patient with perfectly normal organs this might be accomplished by stimulation. But in by far the greater number of patients sepsis has already done the damage by impairing the function of the organs and the added shock of operation still further dissipates the reserve forces. This being the case it is necessary to reduce the demand to a minimum.

Reasoning from the value of antitoxin in diphtheria it is not unreasonable to expect that some form of serum-therapy may be applied to these cases with good results.

Phenol was used in this case, not because I think that it is the ideal, but because it was a substitute by necessity.

I do not mean to give the impression that antitoxin will be a substitute for operative procedure, but be a valuable adjunct.

Another point is the choice of ligature material in septic cases. I think some form of absorbable ligature should be used, and thus avoid sinuses which detract from the otherwise good results of the operation.

Where silk is used it remains as a constant irritant, keeping the sinus open until, in many cases, it is removed.

Clinical Department.

APPENDICITIS IN AN INFANT.¹

BY F. W. TAYLOR, M.D., CAMBRIDGE, MASS.

C. T. L., male, one year and three days old, well developed and unusually well nourished, vomited in the night of February 22, 1897, without known cause. Vomiting was soon followed by loud, prolonged crying, which was repeated whenever the patient was moved. Vomiting, frequent retching, and crying continued throughout the sickness. Nothing was retained by the stomach. The vomitus consisted of mucus, with water or milk if either had been swallowed. Dejections of normal feces occurred February 24th and 25th spontaneously, and on the 26th with intestinal douche. The temperature ranged from 100° to 102° F. The pulse was very rapid. The color was always good. Repeated palpation failed to discover tumor, or to locate pain or tenderness. Distention of the abdomen was slight February 25th. On the 26th it became extreme, but no flatus was passed. In the afternoon the vomitus became brown.

Dr. Charles P. Putnam saw the case in consultation February 26th, about 5 P.M., and confirmed the diagnosis of intestinal obstruction. At 9 P.M. the abdomen was opened in the median line, and the peritoneal cavity found to contain a large amount of thin pus. An incision was at once made over the appendix ceci. The appendix was swollen, red, and attached to the neighboring intestines by adhesions of lymph. It was removed. It had been perforated on the side opposite the mesentery, at about one-third of its length from the tip. The abdomen was flushed with boiled water, and free drainage provided. Death occurred February 27th at 1 A.M.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. THE SECTION FOR OBSTETRICS AND DISEASES OF WOMEN.

C. H. HARE, M.D., SECRETARY.

REGULAR meeting, Wednesday, January 27, 1897,
DR. F. W. JOHNSON in the chair.

DR. PEASE showed

A VERY MUCH ELONGATED UTERUS,

removed by a combined vagino-abdominal operation for extreme vagino-uterine prolapse, which had not been relieved by other modes of treatment.

This was a case on which ventral fixation was done about two months ago, and the uterus came down as much as ever within a month of time of leaving the Carney Hospital. The uterine depth was six inches, and the body could be felt going up towards the umbilicus, the seat of previous operation. The fundus could not be made out with great traction on the cer-

¹ Reported at the meeting of the Cambridge Medical Improvement Society, March 22, 1897.

vix and with the finger in the rectum. A sound in the bladder showed this viscus to reach nearly to the os uteri in front. The cervix itself was not much enlarged except longitudinally, and therefore was not one in which amputation at the cervix would have cured. As she was nearly sixty years of age hysterectomy was decided on as the only means of relief. As the prolapse of the bladder is most difficult to hold up after a hysterectomy, it occurred to me to sew the upper wall of the vagina to the round ligaments after hysterectomy, from the abdomen.

The abdominal operation in this patient was necessary because of probable adhesions from previous ventral fixation. Two years ago I operated on a similar case, but where there had been no previous operation; there I did a vaginal hysterectomy, and at the close of the operation, I sewed the anterior vaginal wall to the broad ligaments at each side. That case has had no trouble with a vaginal prolapse, yet in this sewing from below there was some risk of drawing away my broad-ligament ligature.

In the case of to-day I separated bladder and rectum as high up as I could pull it down conveniently, and then amputated about three inches of the cervix; and having curetted off two large ulcers on each side of the vagina, I sewed the denuded surfaces together, practically doing double lateral colporrhaphy. The stump of the cervix was then sewed together. The abdomen was now opened from above, and the uterus found securely attached for the space of one inch square at the site of the previous operation. The uterus, therefore, though having its os over three inches outside the vulva still had its fundus attached to the abdominal wall, and the ventral fixation did no good, nor would an Alexander have done good. The bowel also was attached for one and one-half inches along the upper line of the incision. This was dissected away, leaving a part of the parietal peritoneum on the bowel. The uterus was now removed from above by cutting and tying the broad ligaments, the round ligaments being tied separately on each side. The upper wall of the vagina was then brought up to what was left of the round ligaments, and sewed to them by silk, care being taken not to tie them so tightly as to produce sloughing. The peritoneum was then caught together except at the middle where a piece of iodoform gauze was allowed to go into the vagina for drainage. The vagina below had previously been caught together with silkworm-gut sutures. In order to perfect the operation, I almost closed the vaginal outlet by refreshing the perineum and putting in three silkworm-gut sutures.

DR. CUSHING: Had this stretching of the uterus occurred since the previous operation, that is, had the uterus elongated since the time it was fastened to the abdominal wall?

DR. PEASE: The previous operation was done by Dr. Mixer, the uterus was held firmly by the good strong adhesions which had been formed. The body and cervix were so long, however, that the os uteri fell fully two inches outside the vulva, although the fundus was held at the abdominal wall.

DR. CUSHING: Is there any record as to its length at that time?

DR. PEASE: The house-officer told me the uterus then was very long and string-like; but exact measurements were not taken. In these cases of hysterectomy for prolapse the question with me has been how

to hold the bladder up securely after the uterus is removed. In an old lady who has passed the child-bearing period, and who is obliged to work for a living, hysterectomy after supports have been tried, seems a most proper operation. It is important, however, that the bladder should be prevented from prolapsing; and, in order to accomplish this result, I know of no better way than to fasten the anterior vaginal wall to the round ligaments after removal of the uterus. As I mentioned before, the case I operated on two years ago has had no prolapse and is doing well. In both these cases there was prolapse of the whole vaginal wall as well as uterus. In both cases different sorts of pessaries were tried before operation was done.

DR. JOHNSON: Did you find the ligature used in suspending?

DR. PEASE: No, sir, I did not. I think usually that ligature is taken out at the end of ten to fourteen days. In dissecting it off, the ligature was not to be seen, but this part was adherent to the scar for a space that large.

DR. CUSHING: Dr. Polk has practised and written about a method by which he fastens the cut end of the vagina up to the abdominal incision. That, of course, is pretty effectual. I don't think the attaching it to the broad ligament or to the round ligament, for that matter, is always sufficient. I have had cases where that has been done, and it has come down unless at the same time thorough anterior colporrhaphy and repair of the perineum is done. In an old woman you can narrow the vagina as much as seems desirable; but the mere hitching of the vault of the vagina to the stump of the broad ligament or to the round ligament will not always hold it unless that is done.

DR. CUMSTON: I should like to show a pedicle needle I had made for me according to my design. In the first place it is made in one piece. It has no eye, simply a slit made in the side of it; and you place the ligature in the slit after the needle has been pushed through the tissues. The slit is made in this sense that, as you withdraw it, the silk does not come out. The ordinary needles have proved unsatisfactory in the large majority of cases, especially when you want to perforate a certain amount of tissue; in removal of the kidney or a large abdominal tumor of any description or operating for goitre or tumors of the neck, it requires a heavy needle. I had this made for me as I wanted it. I had it made on the principle of the amputating knife, that is to say, the handle is as heavy as the length of the blade. It is all made in one piece and can be sterilized. I have found it very satisfactory.

DR. D. P. RONAYNE read a

REPORT OF A CASE OF SUPPURATING OVARIAN CYSTS, OPERATION AND TREATMENT.¹

DR. CUSHING: I think the paper is one of very great interest, and especially the suggestions in regard to the use of some antitoxin for such cases. It has long been evident to me that there was something in regard to the resistance of different patients which could not be accounted for except on the principle that they were immune. For instance, great reputations were early made in the successful removals of pus-tubes and abscesses that were necessarily ruptured into the peritoneal cavity, and yet without fatal re-

¹ See page 480 of the Journal.

sults. I think we must say that all those patients recovered on account of a certain immunity in the woman. We have long ago learned that if the abscess is large enough, and smells bad enough, and the woman is not actually injured in the operation, she is pretty sure to get well, at least not have sepsis. I tried to make some experiments in this line myself, in Paris two years ago, about the serum therapy of staphylococcus infection; but it had not advanced so that any results could be safely deduced from it. I understand it has been used in puerperal fever, etc.; but my impression was that no real results had been obtained. I would like to ask what we are to understand by phenol? Do you mean carbolic acid?

DR. RONAYNE: Phenol is the other name for Edison's aseptine used in phthisis.

DR. CUSHING: Some years ago it was the equivalent of sulpho-naphthol, or creolin. The symptoms would have suggested to me dilating that opening, and investigating whether there was not something collected which needed to be washed out, or running a catheter down and washing out with peroxide of hydrogen. Whether it was the phenol that did this or the discharge of whatever was dammed up is a question. Certainly it is an extremely interesting sequence to the giving of this substance.

In regard to the use of ligatures, I think most of those who have had experience for a good while in foul cases of one kind and another have got to depend on catgut, and have given up silk ligatures for the reason suggested in the paper.

DR. ENGELMANN: This paper recalls the earlier years of abdominal work when we were forced to deal, far more frequently than at the present day, with very large ovarian tumors, and with those in process of degeneration and suppuration; yet I have been fortunate enough to meet with more tractable cases of suppurating ovarian cyst as well, and in one instance only have I seen a condition similar to the one now before us for consideration. The tumor, probably once a multilocular cystoma, now one large sack with disintegrating walls adherent to and in many places closely united with the surrounding viscera, contained a turbid dirty-brown fluid. I was obliged to leave parts of the friable adherent cyst wall *in situ*, and after opening the Douglas, as Martin was then doing, washed freely and drained through the vagina (which I might not now do). Recovery followed after a prolonged struggle, but convalescence was slow. Modern methods would have saved more, such as the one reported, which would appear to have been doomed, but for the "phenol" injections, as indicated by their marked effect on pulse and temperature.

The operator is to be congratulated upon so opportunely seizing on this recent preparation, and upon his success with it at a time when the case seemed hopeless. The remedy is a new one to me, and I shall look with interest for further reports.

DR. CUMSTON: There was one other method, which has been used very considerably of late in Paris, which appears to have given very brilliant results, what Tuffier, who has inaugurated this method in cases of septic conditions such as the writer speaks of, calls "washing of the blood." They inject two or three litres of normal salt-solution into the veins of the arms; and although this may seem an enormous quantity to put into the system, its effect is very remarkable in producing abundant diuresis, which causes

elimination of the toxins and in fact forms a new amount of liquid in the body. I cannot remember the exact number of cases reported by Tuffier in his last publication, but there were six or seven desperate cases, and more than one-half recovered. I simply mention this as another manner of treating septic infection after operation.

DR. JOHNSON: Within the last three or four months I have had two cases of suppurating cyst, one in a young girl fifteen years of age. The tumor, a dermoid, had twisted three times on its pedicle, and the cyst-wall was infiltrated with blood; intestines, omentum and bladder were adherent to the cyst; the temperature 103°, pulse 120; there was also blood in the peritoneal cavity. The cyst was of a dark-green color, about the size of a child's head. The other case was in a patient about fifty years of age, and it was not a dermoid, but the tumor had twisted three times on its pedicle. It was from the right ovary; the other was from the left ovary. She had been sick about a week with severe pain in the abdomen, vomiting, temperature and pulse. Both recovered, had no drawback. Both cysts were of a dark-green color; and in the second case, as in the first, there were adhesions to intestine and omentum.

DR. KINGMAN: I suppose I ought to say something about this paper because I am partly responsible for it, having suggested the use of the tent. I have a case which forcibly brought to my mind the desirability of making this intra-uterine examination before operating. In June I saw a lady about thirty years of age. She was a near relative of a physician who tried for two years to get her to have an examination on account of symptoms that suggested some form of uterine trouble. She agreed to it by reason of a long and painful period. When I saw her she had been flowing ten days. Uterine pain was marked, part of the time of colicky nature, at other times simply aching. On examination I found a symmetrical enlargement of the uterus, firm, hard, suggesting fibroid and extending nearly to the umbilicus. I did not say anything to the patient about it. I was told she was of morbidly sensitive make-up, and that if she heard the word tumor she would refuse operation and go through nameless terrors and suffering. I talked the matter over with the family, and hysterectomy was in prospect. I saw her two days later when she had been relieved of pain, probably in consequence of remedies given, and she was beginning to sit up. I saw her three days later when the pain had returned and there had been a profuse discharge of glairy, stringy material. This rather surprised me, and I made another examination. I found protruding from the vulva some shreds of tissue which looked like the membranes preceding the delivery of the placenta. With this was the brownish, glairy discharge. The vagina was filled with a mass that was the size of a small fetal head, honeycombed completely throughout. This extended through the os to the inside of the uterus. Here was a broken-down fibroid which had retained its contour until after my first examination. The result of the pain had been to dilate the cervix, expel this mass and rupture it. If an operation had been done previous to this spontaneous rupture and delivery the patient would have gone through a hysterectomy to no purpose. She was taken into the hospital and operated upon, the tumor being removed by morcellation. It was not encapsulated, had no line of

demarcation, and was beginning to become putrid. It was tough, resisted curette and everything but knife or scissors. It was trimmed off as closely to the uterus as could be, iodoform gauze introduced, careful cleansing of the uterus being performed by myself every day. The temperature ran to 100° or 101° three or four days after the operation. Then the temperature was normal. She never had any pain. She does not know she had a tumor. The uterus is normal. She is perfectly well, and all her symptoms have disappeared.

This case was very suggestive to me as to the desirability of intra-uterine examination where the contour of the tumor could not be made out upon the outside, and yet where we supposed there was a fibroid. Still I am not a strong advocate of the vaginal operation. I believe that in a small number of cases, strictly submucous fibroids of not too large size should be thus removed, but it seems to me the operation is open to many of the objections I have always felt attach to vaginal hysterectomy. We are handicapped if a sharp hemorrhage starts up. There is more danger of immediate and subsequent hemorrhage than through the abdomen, and it seems to me the added annoyance of a scar and weakened abdominal wall does not compensate for the greater difficulty of the operation by the vagina and for the lessened feeling of security after the operation is done; so that, unless there are strong indications that we can remove the tumor readily through the vagina, I should say go through the abdomen.

DR. E. W. CUSHING: The paper is very interesting, and the reader is to be congratulated on the very successful operation. As I understand it, the main purport of the paper is to the effect that in the recent enthusiasm for vaginal hysterectomy the older operation for removal of submucous fibroids has been neglected, and that the application to that older operation of modern methods of asepsis will in selected cases give very good results and save the uterus. So far I am inclined to agree with him. The operation of vaginal hysterectomy is certainly an easier operation, and there is no doubt a great many men will do it by preference. Looking back in cases you will find, however, that that preference for vaginal hysterectomy rests on a good many rather unpleasant occurrences which have occurred in the attempts in previous times to do the same operation which he describes. I had such a case myself at one time, a fibroid which was submucous and pedunculated. I was removing it in good faith, pulled down a little, turned it round a few times, and it came out—and there was a hemorrhage which didn't stop, and they said the woman was looking badly. I passed a sound, and found the other end up under the abdominal wall; and I suddenly reflected that that fibroid had gone clear through the uterus like a rivet, and I had twisted it out and made a hole. I pulled the uterus down, slipped the clamps on, and had it out in a very few minutes, and there was a pint of blood in the abdomen. In that case I should have lost the woman if I had hesitated five minutes.

Now that brings us to the real difficulty in these cases, which is, in working this way you cannot be sure how thin the partition is between the fibroid which you are removing and the peritoneal wall. If you notice, a good many fibroids as they are removed by hysterectomy, they differ without any particular

rule; one is in the uterus, one in the middle, one on the peritoneal side, one may protrude into the uterine cavity and yet there may be a very thin uterine wall outside of it. One may proceed as the operator has done, remove his tumor with care and skill and discretion, and nevertheless there may have been a perforation which he may know nothing about and which is difficult to find, and the woman will get up sepsis and die. I have a strong suspicion that these cases have happened to a good many men. There was a great deal of this work five to ten years ago. The older books are full of it, and there is very little about it in modern literature, which would imply it has been given up for cause, and the causes are two or three: first, the difficulty of knowing what the other side of the capsule is, how thick it is; and second, in the fact that so many tumors are multiple. As I understand, the reader of the paper rather leaves out the general question of myomectomy abdominally and by the anterior and posterior cul-de-sacs, and limits it to the submucous. I think in a certain number of selected cases, where the tumor bulges into the uterus, is easily accessible and not very large, it can be removed. There is another class of cases where it is something in the nature of a large polyp with a broad base, such as one as Dr. Marcy and I removed and showed here nine years ago, as large as a child's head, where the os uteri was dilated to two or three inches in diameter. We cut it into fourteen pieces and delivered, and the woman got well; but it is not on the whole quite as safe an operation to my mind as vaginal hysterectomy except in very selected cases. Although we ought always to have it in mind and try to save the uterus if we can, and if we are pretty sure the tumor is single and not multiple, yet we have to consider how few the cases are where the tumor is both small and easily come at, and yet of sufficient gravity to necessitate an operation; for if we go to operating on every woman with a little fibroid as big as a marble or an inch or so in diameter, I think we should do a great many really unnecessary operations.

DR. RONAYNE: I remember, in Dr. Emmet's service three or four cases where he attempted to dilate with a tent, and in two cases it had to be removed in ten hours on account of severe pain that was not controlled by morphia, and in all the cases he had to resort to forcible dilatation.

DR. JOHNSON: I agree with the reader that in every case where you cannot make out decided disturbances outside the uterus as a cause for the trouble, that the uterus ought to be examined inside by the finger. I know of three cases where hysterectomy was done, and after the uterus was removed all that was found was a small polypus that could have been twisted off and so put an end to the trouble. I saw one case this winter where the fibroid had undergone carcinomatous degeneration according to the pathologist, Dr. Mallory. He thought it was a fibroid originally which had undergone the cancerous degeneration. I do not agree with the writer that the opening of the abdominal cavity is without danger. I do not think it ought to be put that way. I think it is a more serious procedure. Dr. Joseph Price claims that gonorrhea is a very common cause of fibroid tumors of the uterus. In reference to the statistics on superapubic hysterectomy for fibroids of the uterus, the death-rate is less than one per cent. In the hands of some men it is absolutely nothing.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

FOURTH TRIENNIAL SESSION, WASHINGTON, D. C.,
MAY 4, 5, 6, 1897.

FIRST DAY. — TUESDAY.

WILLIAM H. WELCH, M.D., of Baltimore, President.

This session of the Congress was divided between the American Ophthalmological and American Otolological Societies. The first subject for discussion was

THE GOUTY AND RHEUMATIC DIATHESSES OF THE EYE.

DR. CHARLES STEDMAN BULL, of New York, opened the discussion with a paper dealing with the "Lesions in the Retina and Optic Nerve associated with Gout."

He said that it was worthy of note that endarteritis and endophlebitis were found much more frequently in the retina of persons suffering from an atypical form of gout, than in those who presented the well-known manifestations of the acute type of the disease. The speaker called special attention to three features: (1) the peculiar changes in the arteries, capillaries and veins of the retina; (2) the peculiar localized retinitis, confined to the fundus, with or without hemorrhages in the vitreous, and characterized by a yellowish exudation, occurring in clearly defined patches; and (3) an optic neuritis, occurring generally with, but sometimes without, a retinitis. The subjective symptoms were deterioration in vision, and photophobia characterized by being most marked with artificial light. The ophthalmoscope would show blurring of the outlines of the optic disk, diminution in the calibre of the retinal arteries, occasional fusiform dilatations of the veins, and yellowish patches of exudation, irregularly distributed in the deep layers of the retina. The subject could be briefly summarized as follows:

(1) The changes in the fundus are always bilateral, though rarely symmetrical in the two eyes; (2) the degenerative changes in the walls of the arteries and veins are at first so minute as often to be overlooked; (3) the general angio-sclerosis and retinal patches result in impairment of *central* vision; (4) loss of central vision is progressive up to a certain point; (5) hemorrhages into the retina are chiefly observed in the early stages of the disease; (6) the important feature is the peculiar yellowish, granular exudation in the retina, around the posterior pole of the eye, generally leaving the macula intact until late in the disease; and (7) the changes in the optic nerve are generally intra-ocular.

DR. S. OLIVER RICHEY, of Washington, D. C., continued the discussion, speaking more especially of its relations to glaucoma. He said that the increased intra-ocular tension in glaucoma was due to the distention of the blood-vessels. As far as chronic glaucoma was concerned, the morbid agent of rheumatism could be excluded. Every form of glaucoma was to be attributed to gout or to acquired syphilis in the tertiary stage.

Dr. Richey then called attention to a little-known anatomical point. He said that the *venae vorticosae* pass in the meshes of the sclerotic downward and backward, the shortest being only 1.5 millimetres long, or half as long as the thickest part of the sclerotic. With the high arterial tension associated with gout,

the arteries would become engorged. As a result of even very slight increase in the intra-ocular tension pressure would be made upon the *venae vorticosae*. This, in turn, would give rise to venous stasis, and a still further increase in the intra-ocular tension.

DR. S. D. RISLEY, of Philadelphia, then presented a paper on "Cataract, and its Association with the Gouty and Rheumatic Diatheses." He said that when the lens underwent physiological hardening, and at the same time became opaque, one had strong grounds for believing in the existence of an underlying pathological process, for it was exceptional for senile hardening to be attended with any marked loss of transparency. He was of the opinion that the gouty and rheumatic diatheses were the most common causes of chronic forms of inflammation of the uvule tract. As remarkable changes in refraction were observed in diabetics, as a result of variations in the density of the fluids about the lens, coincident with variations in the quantity of sugar in the blood, it was not unreasonable to suppose that similar changes in the nutrition of the lens might result from the circulation of the poison of gout or rheumatism in the blood.

DR. ROBERT SATTLER, of Cincinnati, then read a paper on "Gouty and Rheumatic Affections of the Uvule Tract." From the author's experience he was inclined to believe that, in this country, at least, iritis and other choroidal complications were very commonly associated with rheumatism. Where gout was the underlying condition, it would be found that, as a rule, the ocular manifestations developed in the early stages of the constitutional disorder. In early gout, one saw "hot eye," but rarely iritis. Experience had taught that the degenerative processes of gout interfered very seriously with operative measures intended to improve or restore the sight.

DR. R. A. REEVES, of Toronto, presented a communication on "Rheumatic and Gouty Affections Involving the Cornea, Conjunctiva and Sclera." He said that in gouty individuals of over forty years of age, it was not uncommon to find a porcelain-like opacity of the cornea, which gave the impression that the sclera had been encroached upon. There was also a variety of gouty episcleritis, characterized by edema, lachrymation, pain and severe photophobia. It occurred in paroxysms of a few days, but the whole course of the disease sometimes extended over a number of years. Episcleritis proper was found in adults of gouty or rheumatic constitution, and should be treated by the internal administration of the salicylate of sodium.

DR. J. M. DA COSTA, of Philadelphia, opened the general discussion. He expressed the belief that four-fifths of all supposed cases of *chronic* rheumatism were not rheumatism at all, and that therefore, we should be careful about assuming too great an influence of chronic rheumatism in eye affections. As we knew a little more about the pathology of gout, there was less liability to error with that disease. In his opinion, there was no such disease as "rheumatic gout." As a general practitioner, he had observed in connection with acute rheumatism chiefly conjunctivitis and iritis. This eye complication was apt to develop at the height of the rheumatic attack—in other words, just at the time when endocardial and pericardial complications were most prone to arise. It was different with gout, for gouty inflammations of the eye occurred in the intervals, as well as with the distinct

gouty attacks. He did not recall having seen a single case in which an eye affection had complicated a rheumatoid arthritis. In patients presenting symptoms of lithemia, first one and then the other would sometimes be affected. This was often associated with headache.

DR. CLARENCE J. BLAKE, of Boston, on behalf of the American Otological Society, delivered an address on

OTOLOGY IN ITS RELATIONS TO GENERAL MEDICINE.

He said that the great vascularity of the auditory canal, drumhead and middle ear in children made these parts liable to become inflamed. In the earaches of childhood attention should be given to the condition of the nose and pharynx, and in cases of the acute exanthemata, the general practitioner should not consider that he had done his whole duty if he had failed to frequently examine the ear. Investigation had brought out the appalling fact that 27 per cent. of the cases of deaf-mutism were the result of suppurative disease of the ear in early life. It should be the duty of the American Otological Society, the speaker said, to endeavor to secure the examination of deaf-mutes by competent aurists, with a view to determining the individual hearing capacities, and hence, the best means of educating these individuals. As it was easier for the aurist to cope with the intra-cranial brain complications of ear affections, this field should be occupied by the aurist, rather than by the general surgeon. In many young women, exhibiting remarkable variations in hearing, examination would show a localized congestion of the tympanic mucous membrane, particularly around the oval window, by the stapes. This was often associated with the menstrual flow. In such cases, the gynecologist was often able to give relief by rectification of pelvic abnormalities.

The subject of vertigo furnished an excellent example of the elucidative work that otology was capable of doing for general medicine. It was now recognized that an effusion or hemorrhage in the labyrinth might affect the balancing power. Such cases were examples of auditory or labyrinthian vertigo. But in many cases it would be found that a mass, or epidermal growth, by pressure on the stapes, might give rise to various symptoms, of which, perhaps, vertigo was the most prominent.

A condition, which should be designated "the fatigue of deafness" was another important matter, but one that received very little consideration. It was to be remembered that persons with normal ears entered life with double the hearing capacity needed for the demands of life. It was in cases of slowly progressive impairment of hearing that this fatigue of deafness was chiefly noticed. Few outside of those who are deaf can appreciate the great effort necessary for persons with impaired hearing to keep themselves in communication with the outer world. Where there is but one act or effort in those with normal hearing, there are, in deaf persons, three acts, namely, (1) hearing, (2) seeing, and (3) understanding.

SECOND DAY. — WEDNESDAY.

This session of the Congress was under the charge of three societies: The Association of American Physicians, The American Physiological Society, and The American Pediatric Society. The subject selected for discussion, was,

INTERNAL SECRETIONS CONSIDERED IN THEIR PHYSIOLOGICAL, PATHOLOGICAL AND CHEMICAL ASPECTS.

DR. WILLIAM H. HOWELL, of Baltimore, contributed the opening paper. He said that Brown-Séquard had revived an old idea in medicine, when he stated his belief that all animal tissues ought to be used in special cases. This observer attributed internal secretions to all tissues, but our present knowledge would seem to indicate that the chief organs having such a secretion were the liver, pancreas, supra-renal bodies, the ovaries, testicles and spleen. The one clearly successful method of treatment by animal tissues was that by the thyroid extracts — a method that had been established quite independently of the generalization of Brown-Séquard. The complete removal of the thyroid in man is followed by serious disturbances of nutrition, resulting sooner or later in death. The fact that extracts of thyroid tissue, when absorbed into the blood, remove or ameliorate the evil effects resulting from loss of function of the thyroid, would seem to indicate that these tissues act normally by giving to the blood something which favorably effects the nutrition of the body — in other words, the thyroid furnishes a true "internal secretion." According to one theory, the secretion is antitoxic; according to the other, or neuro-trophic hypothesis, the secretion of the thyroid acts normally by promoting or regulating the ordinary metabolic processes of the body. Histologically, the para-thyroids do not resemble the thyroids, and appear to have a different origin.

The supra-renals are found constantly in all the vertebrates, and would seem, therefore, to be bodies of fundamental importance. The complete removal of both supra-renals causes extreme muscular weakness, anesthesia and feeble heart action, thus resembling very closely the symptoms of Addison's disease. On injecting an extract of the medulla of the supra-renal body into an animal, the blood-pressure rises, and the heart's action is temporarily slowed. As this effect is not produced if the vagi have been divided, it would seem that the injection of the supra-renal extract stimulates the cardio-inhibitory centre in the medulla. A similar effect is observed when blood drawn from the supra-renal vein is injected into the circulation of a healthy animal. It was interesting to note that Oliver and Schaffer found that the supra-renals in Addison's disease did not contain this substance.

Observations on the function of the pituitary body, the speaker said, had been limited to the anterior lobe, but he had himself recently made some observations with extracts obtained separately from the glandular and infundibular lobes. Extracts of the infundibular portion has a decided effect on the heart, causing a more pronounced and protracted slowing of the heart action than the injection of the supra-renal extract. When the animal was etherized, or when the vagi had been previously severed, this reduction in the rate of the heart action was not nearly so great. Entirely negative results were obtained from injections of the extract from the posterior lobe.

PROF. RUSSELL H. CHITTENDEN, of New Haven, discussed the physiological and chemical aspects of the subject. He stated that there must be a close similarity in function in the case of the thyroid and para-thyroids, for experiment had clearly shown that

in animals possessing para-thyroids, the thyroid and all but 40 per cent. of the para-thyroids could be removed without causing the death of the animal. The administration of thyroid gland and thyroid extracts to normal individuals produced a very noticeable effect on the metabolism of the body, leading to a marked loss of body-weight, and to increased excretion of phosphoric acid, nitrogen and water. It had also been shown that the thyroid was concerned in hematosi. After thyroidectomy, there was an increase in the mucin in the body, especially in the salivary glands. It was to be presumed that the toxic products were formed, not in the thyroid, but in the tissues of the body as a result of perverted metabolism due to atrophy or alteration in the thyroid gland. The thyroid gland is especially characterized by the presence of a compound proteid of peculiar constitution. This substance, to which Hutchin-on gave the name of "colloid matter," is the active constituent of the gland. There are also present a small quantity of nucleo-albumin and certain extractives, but the latter seem to be without physiological significance. Interest centred chiefly around this colloid matter, which contained a compound known as "iodo-thyrine." In human thyroids, and in the thyroid of sheep, oxen and pigs, iodine is present even to the extent of ten per cent., yet so far as known, it is not normally present in other tissues. In cases of goitre only minimal and relatively small amounts of iodine are found. These facts would seem to indicate that the iodine contained in iodo-thyrine was an important element, but this view is controverted by the fact that a dose of only one milligramme of iodo-thyrine would produce a distinct effect on goitre, and also by the fact that the thyroids of some children do not contain an appreciable quantity of iodine. The speaker, in closing, said that there was some evidence that there were two distinctly physiologically active substances in the adrenals. In extracts of the testis, a peculiar nitrogenous body had been separated, to which the name of "spermine" had been given.

DR. J. GEORGE ADAMI, of Montreal, on behalf of the Association of American Physicians, discussed the pathological aspects of the subject. He said that assuming that the glands of the body possess an internal secretion of physiological activity, we must recognize the possible existence of three orders of conditions, namely, (1) glandular inadequacy, (2) glandular overactivity, and (3) compensation. In the first two divisions there were changes accompanied by symptoms, but not so in the third division. It was difficult to discuss internal secretions from this standpoint because of the rarity with which the pathological findings permitted one to draw conclusions regarding what had been the functional activity of the various organs during life.

DR. FRANCIS P. KINNICUTT, of New York, said that the use of thyroid preparations in myxedema had given very encouraging results, and had demonstrated that complete recovery could be effected by this remedy, even in severe cases of long standing. But experience had also shown that it was necessary to continue the use of the remedy throughout the lifetime of the patient. In sporadic cretinism administration of the thyroid extract caused a rapid disappearance of the symptoms of myxedema, and a striking improvement in both the mental and skeletal development. If begun sufficiently early in the child, there

was now every prospect that the treatment was capable of causing a cretin child to develop into a healthy adult. It should be borne in mind that the degree of improvement effected in goitre depended upon the variety. The best results were obtained in simple hyperplastic goitre, and the least benefit was observed in the cystic goitres. There had already been some experience reported which was favorable to the use of the thyroid preparations in certain forms of mental disorder. The remedy had become very popular in the treatment of obesity. It was true that it often caused a very rapid and marked diminution in the body-weight without deterioration of the general health, but the obesity returned very soon after the discontinuance of the thyroid extract. He had personally investigated the claims made for thyroid extract in the treatment of phthisis, but his experience with it had been entirely negative. Of 48 cases of Addison's disease treated with extracts of the adrenals, 6 had been reported as cured, 22 as improved, 18 unimproved, and 2 as made worse by the treatment.

DR. JAMES J. PUTNAM, of Boston, spoke of the relation of infantilism to myxedema, and of acromegaly, giant growth, and similar affections to loss or perversion of the function of certain glands, such as the pituitary body, the thyroid, the adrenals and the testes.

DR. WILLIAM OSLER, of Baltimore, then exhibited a series of lantern slides illustrating the remarkable results obtained in the treatment of cretinism by thyroid preparations.

THE PRESIDENT'S ADDRESS.

DR. WILLIAM H. WELCH, of Baltimore, the President of the Congress, delivered his Address in the evening before a large audience, taking for his subject

THE ADAPTATION OF PATHOLOGICAL PROCESSES.

He said that the most wonderful and characteristic attribute of living organisms was their adaptation to external and internal conditions in such a way as to promote the welfare of the individual or the species. Familiar examples of this were to be found in the preservation of the body temperature amid varying conditions, the adaptation of the heart to the changing demands upon it, and the adjustment of the iris to different degrees of illumination. The mechanical theory of the purposefulness observed in Nature was the only one that could be recognized in science. One of the most important characteristics of pathological adaptations was that they had their foundation, for the most part, in physiological processes or mechanisms. As an illustration of the fundamental principles of pathological adaptation the speaker selected cardiac hypertrophy. Physiologists had shown that the heart responded to the increased demands made upon it, by reason of an embarrassed circulation, because these circulatory disturbances increased the tension on the cardiac muscle in much the same way as a weight augments the tension on a voluntary muscle. But with a given stimulus, and with increased muscular tension, a point is reached at which the contraction is diminished, although the actual work done is increased. The result is dilatation of the heart; hence, dilatation often precedes the compensation. This dilatation lessens the strain on each muscular fibre, and so enables it to shorten more with each contraction.

But some kinds of excessive work, it should be noted, did not lead to hypertrophy. An example of this was to be found in an unusually rapid heart action, which might last for years without causing cardiac hypertrophy. Clinical experience showed that the reserve force was less in the hypertrophied than in the normal heart. The regulation of the velocity and volume of the circulation furnished another example of adaptation. Again, the clinician was not likely to look upon inflammation as a beneficent process, but the pathologist saw in it a protective process by which invading micro-organisms might be kept out of the system.

Dr. Welch said Nature was neither kind nor cruel, but simply obedient to law, and therefore consistent. Her healing power was often incomplete and imperfect; hence too much reliance should not be placed on systems of treatment based on Nature's curative powers.

THIRD DAY.—THURSDAY.

CONGENITAL DISLOCATION OF THE HIP.

DR. E. H. BRADFORD, of Boston, on behalf of the American Orthopedic Association, opened the discussion on this subject, illustrating the various conditions by lantern slides. Speaking of the diagnosis, he said that congenital dislocation of the hip was not likely to be confounded with other conditions, unless it might be coxa-vara. In the latter, however, the gait was unlike that so characteristic of congenital dislocation. In operating on these cases, the best line of incision was that employed by Lorenz, namely, one passing from the anterior superior spine of the ilium obliquely downward along the outer edge of the tensor vaginae femoris and anterior edge of the gluteus medius muscle. The femoral head and acetabulum having been exposed, the acetabulum was curetted until sufficiently deep to receive and retain the head of the femur. The reduction of the dislocation was often rendered difficult by the surgeon failing to freely divide the attachment of the capsule to the lesser trochanter.

Dr. Bradford said that a new method of treatment, also devised by Lorenz, was now being given a trial. In this, no incision was made, but the child was subjected to a preliminary stretching for several days. The child should be placed in a horizontal frame, and the limb gradually abducted at the same time that traction was made. The object of this is to stretch the shortened capsule. After a few days of this stretching, the child was placed under an anesthetic, and the limb subjected to traction at right-angles to the body. He had found that this could be most conveniently done by means of a Thomas splint with a windlass attachment at its inferior extremity. The limb should next be flexed and abducted, and, while in this position, put up in a spica bandage of plaster-of-Paris. After a week or two the child should walk on crutches, being instructed to keep the leg slightly abducted. In concluding his remarks, the speaker stated his belief that congenital dislocation of the hip, coming under treatment between the ages of two and five years, was a curable condition.

DR. V. P. GIBNEY, of New York, said that he was sorry he could not share Dr. Bradford's hopeful views regarding the results of treatment in congenital dislocation of the hip. At one time he had treated these cases according to the mechanical method advocated by Dr. Buckminster Brown, of Boston, and he thought

he had obtained in this way one or two good results. At the present time, he was obliged to say that he did not know of any case in this country in which the patient did not continue to limp after either the Hoffa or Lorenz operation. Moreover, he had known this operative treatment to be followed by chronic suppurative arthritis of the hip. The preliminary stretching was very important.

DR. HARRY M. SHERMAN, of San Francisco, spoke of the operative treatment of congenital dislocation of the hip from the standpoint of one who had been an eye-witness of the method as employed by Lorenz himself. Lorenz uses a sharp-pointed knife in entering the capsule of the joint, and then a large knife, shaped like a tenotome, to still further divide the capsule. He next introduces his finger into the capsule, and with it as a guide, curettes out the acetabulum. While this part of the operation is being done, traction is made by means of a traction apparatus and aseptic towels placed around the groins and hips. After the reduction of the dislocation, a drain of iodoform gauze is inserted into the joint, and superficial sutures used to close the wound. The leg is then extended and markedly abducted, and while in this position both limbs are put up in plaster-of-Paris, and kept firmly apart by a cross-piece of wood. After six weeks, this apparatus is removed and the child allowed to walk. At first, there would usually be free motion at the hip, but this would gradually diminish, and if massage and carefully-planned exercises were not carried out for six months flexion and abduction would probably ensue. In closing, Dr. Sherman said that he believed that with further experience and improvement in the technique, the Lorenz operation would yield satisfactory ultimate results.

The latter part of this session of the Congress was in charge of the American Surgical Association.

THE CLASSIFICATION OF ACUTE GENERAL PERITONITIS; THE PROGNOSIS AND TREATMENT OF THE DIFFERENT VARIETIES.

DR. NICHOLAS SENN, of Chicago, opened the discussion with a paper in which he presented a "Classification of Acute Peritonitis," as follows:

1. Anatomical Classification: (a) Ecto-peritonitis, (b) endo-peritonitis; (c) parietal peritonitis; (d) visceral peritonitis; (e) pelvic peritonitis; and (f) diaphragmatic peritonitis.
2. Etiological Classification: (a) Traumatic peritonitis; (b) idiopathic peritonitis; (c) perforative peritonitis; (d) metastatic peritonitis; (e) puerperal peritonitis; (f) peritonitis infantum (fetal, intra-uterine peritonitis and peritonitis neonatorum).
3. Pathological Classification: (a) Diffuse septic peritonitis; (b) putrid peritonitis; (c) hemorrhagic peritonitis; (d) suppurative peritonitis; (e) serous peritonitis; and (f) fibrinoplastic peritonitis.
4. Bacteriological Classification: (a) Streptococcus infection; (b) staphylococcus infection; (c) pneumococcus infection; (d) bacillus coli communis infection; (e) gonococcus infection; (f) tubercular infection.
5. Clinical Classification: (a) Ecto-peritonitis; (b) diffuse septic peritonitis; (c) perforative peritonitis; (d) circumscribed peritonitis; (e) hematogenous peritonitis; (f) visceral peritonitis; (g) pelvic peritonitis; (h) puerperal peritonitis; and (i) subdiaphragmatic peritonitis.

Ecto-peritonitis, the speaker said, was an inflammation of the attached side of the peritoneum, as distinguished from inflammation of the serous surface. This inflammation of the sub-endothelial vascular con-

nective tissue was characterized clinically and pathologically by intrinsic tendencies to limitation of the inflammatory process. In certain localities, however, it might become quite diffuse, as when the cavum Retzii or the retro-peritoneal space on either side of the spinal column was the seat of suppuration. In infected wounds of the abdominal wall, in which the peritoneum was exposed, but not perforated, the primary ecto-peritonitis was occasionally followed by extension of the infection to the serous surfaces through the lymphatics, or by the direct extension of the infective process through the tissues to the endothelial lining. Peritonitis of visceral origin is always preceded by ecto-peritonitis.

Parietal peritonitis may occur as a primary affection in penetrating wounds of the abdomen, but more frequently as a secondary disease in consequence of the extension of an infection from one of the abdominal or pelvic viscera, or perforation into the peritoneal cavity of a visceral ulcer, or of a subserous or visceral abscess.

By "visceral peritonitis" is meant an inflammation of the peritoneal investment of any of the abdominal or pelvic organs. As the mesentery and omentum are modified anatomical forms of the peritoneum, when they are inflamed, the process is spoken of as a mesenteritis and an epiploitis respectively.

As peritonitis is always the result of infection with pathogenic microbes, usually of the pyogenic variety, an etiological classification must take cognizance of the various avenues through which the microbes find their way into the peritoneal cavity.

The term "idiopathic peritonitis" indicates a peritonitis without antecedent injury or suppurative lesion. It is exceedingly rare — indeed, by many its very existence is doubted. Probably future bacteriological examinations of the inflammatory product will reveal a microbe cause in all such cases.

Perforative peritonitis is a very common variety. Experimental research has shown that the intestinal wall, when paretic or gangrenous, becomes permeable to the microbes contained in the intestinal canal. In many cases of intestinal obstruction, death results from septic peritonitis after the intestine has become paretic or gangrenous. Metastatic peritonitis is seldom seen except as a lesion associated with pyemia.

In puerperal peritonitis the infection may extend from the endometrium through the Fallopian tubes, or it may follow the lymph channels or the thrombosed uterine veins.

Intra-uterine peritonitis is most apt to occur between the seventh and ninth month of utero-gestation, and frequently proves fatal to the fetus. It is often associated with syphilis. Peritonitis neonatorum is met with most frequently in children of women suffering from puerperal fever. The infection takes place through the imperfectly healed umbilicus.

The pathological classification, Dr. Senn said, was based almost entirely on the gross and microscopical appearances of the exudation and transudation. The term "diffuse septic peritonitis" should be restricted to those cases in which, as a rule, death occurs in a few days, and before any gross pathological conditions have had time to form. The microbes which produce this form of peritonitis are those which follow the lymph spaces and are rapidly diffused, not only over the entire peritoneal surface, but also through the subserous lymphatic channels. Putrid peritonitis is

characterized by a brownish, fetid product, and occurs most often in grave forms of puerperal metritis. Hemorrhagic peritonitis occurs most frequently in the pelvis, upon the posterior surface of the uterus and vagiua, and, in men, behind the bladder. The inflammatory product consists of brown patches composed of delicate and very vascular villi. Sero-purulent peritonitis is always associated with fibrinous exudations which tend to limit the extension of the infective process. Serous and fibrinoplastic peritonitis are due to a mild infection, and are ordinarily more or less limited by firm adhesions.

In considering the bacteriological classification, streptococcus infection must be given first place. This is the microbe most frequently found in septic peritonitis. Absence of fibrinous exudate and effusion are the most striking negative findings at operations and autopsies. In staphylococcus infection the intrinsic tendency to localization of the process is more marked. Occasionally, the diplococcus of pneumonia is the bacteriological cause of acute suppurative peritonitis. In cases of intestinal paresis or perforation, the colon bacillus escapes into the peritoneal cavity and gives rise to suppurative and fibrinoplastic peritonitis. In the peritoneal cavity, the gonococcus produces a plastic peritonitis, and sometimes localized suppuration. Depending upon the intensity of the infection and the susceptibility of the patient, the tubercle bacillus gives rise to (1) tubercular ascites, (2) fibrinoplastic peritonitis, and (3) adhesive peritonitis. Suppuration only takes place when the tubercular product becomes the seat of a secondary mixed infection with pus microbes.

The clinical classification, Dr. Senn said, must be based on the information already obtained from the classification. For example, ecto-peritonitis is associated with abscess formation of the subperitoneal connective tissue, most frequently in the pelvis of women, and the cavity of Retzius in men. It is not infrequently followed by extension of the infection through the lymphatics to the free surface, thus exposing the patient to the risk of perforation of the abscess into the free peritoneal cavity, diffuse septic peritonitis and death. Again, diffuse septic peritonitis is a common result of penetrating wounds of the abdominal cavity, complicated by visceral lacerations of the gastro-intestinal canal, contusion or laceration of any of the abdominal or pelvic organs, or perforation of a septic lymphangitis from any of the visceral or pelvic organs to the peritoneum. The march of perforative peritonitis is usually marked by the sudden onset of the symptoms — diffuse tenderness, rigid abdominal walls, fever, vomiting — and by the impossibility of ascertaining by inspection, palpation and auscultation, the presence of intestinal peristalsis. This last sign is almost positive proof of the presence of gas in the free peritoneal cavity. Among the more common causes of circumscribed peritonitis are, appendicitis, cecitis, perforating ulcer of the stomach and inflammations about the gall-bladder, Fallopian tubes and ovaries. A form of inflammation of the peritoneum, called "hematogenous peritonitis" has been observed in connection with nephritis, pyemia, rheumatic arthritis and the acute exanthemata.

DR. ROBERT ARBÉ, of New York, spoke of "The Prognosis of the Different Varieties of Peritonitis." He said that it was now generally admitted that every

case of inflammation of the peritoneum was due to some septic micro-organism, but as yet no definite relation had been established between specific forms of micro-organisms and particular types of inflammation of the peritoneum. An interesting point in connection with both the prognosis and treatment was that it had been shown experimentally, and confirmed clinically, that the peritoneum was capable of absorbing from three to ten times the body-weight in an hour. In many regions, inflammation of the peritoneum is a limited process from beginning to end. This is particularly true of inflammation of the peritoneum about the stomach, gall-bladder and uterine appendages. It is much more apt to be diffuse if it originates in middle portion of the abdominal cavity.

The influence of the particular region involved upon the prognosis was well shown in the statistics that had been collected by Dr. Robert F. Weir regarding cases of operation for perforating ulcer of the stomach. He found that out of 97 such cases, 22 recovered. An equally favorable prognosis could now be given in cases of gunshot injuries of the abdomen provided there was not much delay about operating. If the operation were done within twelve hours, half of the cases would recover; if delayed over twenty-four hours, not more than 25 per cent. of recoveries should be expected. Recent statistics showed that even in cases of peritonitis due to perforation of a typhoid ulcer, 26 per cent. recovered. This was indeed a great improvement on the statistics of only a few years ago. If appendicitis cases were not treated by the general practitioner with hopeless expectancy for days before calling the surgeon to his aid, the prognosis in this class of cases would soon be vastly better than at present.

DR. GEORGE R. FOWLER, of Brooklyn, spoke of "Septic Peritonitis considered from the Clinical Standpoint." He said that peritonitis might occur without the actual presence of bacteria, as, for example, when their toxins penetrated the visceral walls without producing any actual lesion, and thus reached the serosa. The least dangerous mode of entrance was in connection with a wound of the abdominal wall. Important elements in the prognosis were: source and virulence of infection, mode of entrance, concomitant circumstances, the presence of hemorrhage or serous exudation, and whether or not the infection were localized. It should be remembered that the serous effusion in the peritoneal cavity possessed a certain germicidal power.

Referring to treatment, the speaker said that during the last ten years several cases of diffuse septic peritonitis had been operated upon successfully. From our present bacteriological knowledge it was difficult to conceive of a case in which the patient's doom was sealed from the very commencement; hence the responsibility of the surgeon was enhanced. Dr. Fowler said that from his observations in one case in which he had used the streptococcus antitoxin in an effort to control a diffuse septic peritonitis, and from a study of several other reported cases, he felt doubtful as to the influence exerted by the serum over this form of peritonitis. The matter must still be considered *sub judice*.

DR. ANDREW J. MCCOSH, of New York, objected to Dr. Senn's classification of acute peritonitis on the ground that it was too elaborate for clinical purposes. For example, it was next to impossible to distinguish clinically diffuse septic, putrid and suppurative periton-

itis. The bacteriological division was the most definite and satisfactory of the classifications offered. In making a prognosis in a case of peritonitis, he was inclined to give much weight to the duration of the process, and the individual resisting power, as determined by the age and other elements. Of his successful cases, in none had the patient been over thirty-five years.

In considering the treatment of peritonitis, Dr. McCosh said he could not agree with those who would divide the cases into two classes—those requiring sponging or swabbing, and those demanding irrigation—for the reason that in some of the most virulent forms of peritonitis the gross appearances would rather indicate, in many instances, a mild grade of inflammation. It seemed to him, therefore, safer to regard every case as exceedingly grave, and treat it by irrigation. It was true that this did not remove all the septic matter, but it had been shown, both by experimental investigations and by clinical experience, that this was not necessary. Moreover, the scrubbing process must inevitably injure the peritoneal endothelium, and diminish by just that much its powers of resistance. It also favored the migration of the bacillus coli communis through the wall of the intestine into the peritoneal cavity. The speaker said that for the past year or two he had made it a rule to draw out the intestinal coils into *hot* towels, and to cleanse them by pouring over them large quantities of hot sterilized salt solution, at the same time irrigating the abdominal cavity, by means of a hose, with the same solution. The salt solution should have a temperature between 110° F. and 115° F., as even this high temperature was not harmful to the peritoneum, while it acted as an excellent stimulant to the heart. By leaving considerable of this solution in the peritoneal cavity, the circulation would be still further stimulated, and the flow of septic material would be excited in the direction of the intestine, instead of from the bowel into the peritoneal cavity. As for opiates, he mentioned them only to condemn their use in peritonitis. His own experience had led him to feel that the safety of the patient depended largely upon his ability to prevent intestinal paralysis and to promote intestinal peristalsis. Accordingly, he usually gave one dose of ten grains of calomel shortly after the operation, and followed this by injecting high up in the *small* intestine an ounce or two of sulphate of magnesium. He used a medium-sized aspirating needle and an antitoxin for making these intra-intestinal injections, and used a saturated solution of the sulphate of magnesium. He felt positive that some lives had been saved by this means. From January, 1896, to March, 1897, he had operated upon eight cases of diffuse septic peritonitis, with six recoveries. In all but one of the cases the peritonitis had apparently existed for more than twenty-four hours before operation, and most of the cases showed an advanced stage of septic inflammation. In the matter of drainage, Dr. McCosh said it was his practice to use several strips of gauze, projecting in different directions among the coils of intestine. Sometimes he used strips of rubber tissue, or strips of pure silk sponge. The latter had the advantage of being easily removed. Rubber drainage-tubes were more liable to become obstructed than glass tubes. Success in the treatment of general septic peritonitis depended chiefly on early operation, thorough irrigation, efficient drainage and promotion of intestinal peristalsis.

ASSOCIATION OF AMERICAN PHYSICIANS.
TWELFTH ANNUAL MEETING, WASHINGTON, D. C.,
MAY 4, 5, 6, 1897.

(Concluded from No. 19, p. 470.)

SECOND DAY. — WEDNESDAY.

DR. A. MCPHEDRAN, of Toronto, read a paper on
PANCREATITIS FOLLOWED BY CYST OF THE PAN-
CREAS.

The patient came to him in 1891 with pain over the right abdominal region. He treated him, and during the next five years he had repeated attacks of pain, which became more frequent. Gall-stones were diagnosed, and an operation was advised. On September 6th he suffered from colic, prostration, vomiting and extreme pain lasting for three days; his temperature was 101°. After this he began to improve, but was still uncomfortable; his diet was regulated and Carlsbad salts prescribed. On October 8th a large cyst was discovered over the epigastrium, extending to the right over the pancreas; his temperature was 99.5°. He was operated on, and a clear serous liquid was drawn off. At the bottom of the wound the pancreas was felt enlarged and hard; the liver was healthy, the gall-bladder was not reached. The opening was closed without drainage; pulse, 130; temperature, 101.5°; extreme cyanosis and dyspnea. Ten days later a thick fluid, purulent in character, came from the lower border of the wound; it was probably the result of fat necrosis. The pancreas seemed to have increased in size.

Later the patient improved, but his digestion continued disturbed, and he suffered from flatulence. The tumor grew forward, and pushed the colon below and the heart above. The urine was free from sugar. In March another operation was performed, and a cyst with walls two millimetres in thickness was laid open. The fluid was thick, flocculent, contained albumin, and was outlined; and there seemed to be no digestive ferment present in the fluid. The patient recovered; but a fistula persisted, and the discharge was free and the skin was excoriated. The fluid now seemed to possess some digestive powers. The general health of the patient was good, but the sinus persisted and the discharge still continued. The first attack and the subsequent ones were undoubtedly due to the beginning of the trouble in the pancreas. As Fitz has shown, there are three forms of pancreatitis: the simple, the hemorrhagic and the purulent.

DR. J. H. MUSSER, of Philadelphia, read a paper entitled

ANGINA PECTORIS: ITS RELATION TO DILATATION
OF THE HEART,

which was entirely clinical. The contention of the paper was to the effect that patients who have had an attack or attacks of angina pectoris are relieved of the paroxysms if dilatation of the heart supervenes. Often, if dilatation persists, the patient may live for years, and no other paroxysms occur. It seems the pain, as long ago pointed out, is due in large part to the stretching of a tense ventricle from intra-cardiac pressure. Such stretching is not so likely to occur in dilatation because of "safety-valve action" in the heart. The idea appears to explain the infrequency of angina in the young; in mitral valvulitis with regurgitation; in women, possibly; and in the occupants of infirmaries

and hospitals. In the latter class the vigor of the heart muscle is lessened from lack of food, etc., which obtains in the better class. Certainly it is not because of the absence of atheroma of the coronary arteries, for endarteritis is very prevalent among senile, usually alcoholic, perhaps syphilitic inmates of the hospitals and almshouses.

If the contention is true, the diagnosis, prognosis, and the treatment tentatively admitted, are influenced thereby. The diagnosis is that angina-like paroxysms in dilatation of the heart are probably not due to true angina pectoris. The prognosis is that, if, as rarely happens, an undoubted attack of angina occurs in a case of valvulitis with dilatation, and even failing compensation, the patient, on the one hand, is not likely to perish from the angina, because of the safety valve, while, on the other hand, it indicates that there is sufficient strong muscle fibre to ensure cardiac recuperation. Further, if a patient subject to attacks of angina presents signs and symptoms of dilatation, the angina will disappear, or at least never be so severe as to terminate fatally. That the pain is due to intra-cardiac pressure is more possible because of the presence of dilatation of the heart in angina *sine dolore*. Attention was called to a similar association of pain with increased tension of the globe in acute glaucoma. In connection with the above the writer showed the influence of "safety-valve action" in the relief of some peripheral symptoms of high arterial tension.

DR. WHARTON SINKLER, of Philadelphia, said that the question of the cause of the pain in this trouble was of great interest, and Dr. Musser's explanation did not seem to be sufficient. There is also a pseudo-angina which is very painful and he cited a case of this disease in a young woman in whom one grain of morphia failed to relieve the pain. There was no evidence of disease of the heart at any time. The case finally recovered.

DR. H. C. WOOD, of Philadelphia, asked what was the cause of the increased intra-ventricular pressure in these cases. It cannot come from any condition of the heart itself. If angina pectoris is due to increased intra-ventricular pressure, we should expect the arterial system to play the chief rôle, and not the heart. Nitrite of amyl is interesting in this connection, for it relieves the angina and takes away the resistance of the heart. Digitalis has a very curious action, and the subsequent effect is not good. If this theory holds, then the angina pectoris could be stopped by a hypodermic injection of the nitrite of glycerine. If you give enough aconite you could do away with intra-ventricular pressure altogether. In some conditions digitalis does great harm to the heart in angina pectoris.

DR. E. G. JANEWAY, of New York, mentioned some cases in his practice. A man who was frightened in an accident on the railroad, suddenly had a severe pain in the right side and not the left, and was ashy pale. He later had pericarditis, and a diagnosis was made of thrombosis of the coronary artery with partial rupture of the heart. He was at first feeling a little better, when one day he suddenly sat up in bed and fell over dead. At the autopsy there was found a rupture of the septum of the left ventricle and a soft clot there, and thrombosis of the right coronary artery.

Dr. Musser's theory does not explain every case. Another patient was walking through a field, when he had a sudden attack of angina pectoris for the first

time; he died three weeks later. As no one had seen this attack, and as his death took place at night, poisoning was suspected; but the autopsy showed that both coronary arteries were diseased, the left one having been affected earlier than the right. Dr. Janeway had had some cases of low arterial tension in which nitroglycerine rather did harm; these were not true anginas but cardiac strain.

DR. CHAS. CARY, of Buffalo, said that the increased tension in glaucoma was in a certain sense a parallel to the intra-ventricular pressure with angina; but he doubted if Dr. Musser's theory was entirely correct and the whole thing was open to question.

DR. MUSSER said, in reply, that he did not mean to refer all cases of angina pectoris to this cause, but he wished to lay special stress on the fact of the safety-valve action of the mitral valve by which all pain was decreased. It was not his object to explain all the causes of the pain by this theory.

DR. F. P. KINNICUTT, of New York, said that Dr. Musser's theory might explain some cases, but he had seen certain conditions of the heart in which there was great pain from stretching of the heart walls.

DR. F. C. SHATTUCK, of Boston, read a paper on

PERICARDITIS, SOME POINTS ON ITS DIAGNOSIS AND TREATMENT.

He said that this disease though well known was often overlooked because it was not sought for. Rheumatism was the principal cause. Endocarditis and pericarditis may coexist. In many cases, especially in children, the physician does not see the beginning of the disease. It may come from pneumonia; indeed, pneumonia and pericarditis are often more associated than is commonly supposed. Of 57 cases in his service at the hospital during the last three years there were 20 autopsies, in 13 of these pericarditis was found, five being detected during life, and in eight it was not discovered though carefully sought for. Symptoms are not to be relied on, because if the effusion is small or absent there are no signs or symptoms to indicate the disease. If the primary disease is severe, it may mask the complications. The less severe the original disease the more likely are symptoms of complications to be found. Though the diagnosis must rest mainly on the physical signs, these may be absent. The friction murmur is very evanescent, and may come and go between the examinations. He thought that the shape of the dulness was not pyriform or triangular but similar to that of general enlargement of the heart. He reported eight cases.

Treatment other than rest is of little use. Opium is indicated for pain and alcohol for stimulation. In his opinion blisters were of no use. Ice packs might be used for the comfort of the patient. He had tapped six patients successfully, and feels sure that he had saved the lives of two. Absorption might follow the removal of a small amount of the liquid. There is no hard and fast rule as to when to tap; each case must be treated on its own merits. The point of election for tapping was in his opinion in the fifth interspace, one to two inches to the left of the left nipple, or just inside the left limit of the line of dulness. In one case he had drawn away 16 ounces, again 24, and in another 36.

DR. JAS. T. WHITTAKER, of Cincinnati, spoke of the latency of the disease, and said it was often unrecognized until the post-mortem. He thinks that a

collection of a large amount of clear fluid in the pericardium is due to tuberculosis in many cases. He was able to locate and map out the effusion by letting the stethoscope hang in his ears just touching the chest wall of the patient, who is in a recumbent position. He taps every case he suspects, and often succeeds in finding fluid in the second or the sixth left interspace when he cannot find it anywhere else; he always feels the heart pulsate against the trocar and then withdraws it slightly.

DR. G. L. PEABODY, of New York, spoke of a case in which he had passed the trocar in, and the canula had become stopped by a piece of cartilage.

DR. H. A. HARE, of Philadelphia, said the danger of hurting the heart muscle was not very great. He had made the experiment of stabbing a number of dogs in the heart, and had found that the results were never fatal unless the heart centres were wounded, which was very seldom done. He killed these dogs after a certain time, examined their hearts, and found in every case the wound had healed with very little blood in the pericardium. He spoke of a man with articular rheumatism and pericarditis whom he tapped twice; he pierced the heart each time and drew blood. The man felt better, though he subsequently died. At the post-mortem he found the wound in the heart healed.

DR. T. M. ROTCH, of Boston, said that Dr. Hare's experience agreed with his. It is often hard to make a diagnosis, and the usual signs sometimes fail; but he found that the heart was floated up by the effusion, therefore the tapping was done below, for it was better to avoid the heart if possible. He referred to a case in which he had tapped the pericardium through the back near the angle of the scapula.

DR. NORMAN BRIDGE, of Los Angeles, Cal., reported several cases in which there was very little effusion and in which the diagnosis was extremely difficult.

DR. JAS. TYSON, of Philadelphia, referred to the outline of the effusion. He differed somewhat from Dr. Shattuck. He thought we did get a pear-shaped dulness on percussion. He had found the phonendoscope very useful in mapping out organs in ordinary heart disease; he thought it would prove to be a useful instrument in this respect. He did not agree with Dr. Shattuck in doing away with the blister. He was inclined to stick to the blister, for it sometimes saved tapping. He had never tapped a pericardium. When Dr. Shattuck had finished his paper he felt bold enough to tap any pericardium; but since the other members had spoken, his courage had oozed out and he was back in his old position.

DR. A. MCPHEDRAN, of Toronto, thought that myocardial infection should be considered. It is often the chief disease.

DR. F. H. WILLIAMS, of Boston, said that the x-rays had been useful in making a diagnosis of pericarditis.

DR. E. G. JANEWAY, of New York, thought we could always make out the pyramidal shape of the pericardial effusion. In one case in which the heart was punctured, the patient had died.

DR. SHATTUCK said, in conclusion, that he had had only one case in which no fluid was obtained. Some dry taps were afterwards productive.

DR. M. HOWARD FUSSELL, of Philadelphia, read by title a paper on

PNEUMONIA IN PRIVATE PRACTICE.

This paper embraced a series of cases treated privately, in which accurate notes had been kept. They were analyzed, and deductions as to mortality, symptoms, physical signs and treatment were made.

DR. BEVERLY ROBINSON, of New York, read a paper on

DIAGNOSTIC AND THERAPEUTIC CONSIDERATIONS WITH RESPECT TO CERTAIN DISEASES OF THE UPPER AIR TRACT.

He spoke of the utility of the laryngoscope and rhinoscope in making a diagnosis. He said that throat specialists in using these means first began to look for deviated septa and enlarged turbinates, which were respectively cut, cauterized, etc.; then a reaction set in, and it was concluded that deviated septa and enlarged turbinates should be let alone. The specialist should remember not to treat the nose and throat alone, but to look after the general condition of the patient. The great contrast between the general practitioner and the specialist in the treatment of the diseases of the upper air tract was that one looked too much after the general health and neglected local treatment, while the other paid too much attention to the local causes and forgot about the rest of the body.

DR. J. E. GRAHAM, of Toronto, reported

TWO CASES OF BRONCHO-BILIARY FISTULA.

One was a further history of a case of broncho-biliary fistula which was reported at the first meeting of the Association. A second attack occurred after an interval of ten years. The patient coughed up large quantities of bile, almost daily for a period of eight months; there was great loss of flesh and strength. A cholecystostomy was done. Gallstones were found. Death from cholemia and hemorrhage followed. Short notes of some similar cases, and notes of a second case of broncho-biliary fistula, in which the lesion followed a traumatism, were given.

DR. J. C. WILSON, of Philadelphia, reported

A CASE OF NERVOUS DEAFNESS IN DIPHTHERIA.

He gave the following abstracts: Follicular tonsilitis in an adult; moderate fever, occipital headache, tinnitus aurium et cerebri; fourth day, dense pellicular exudate upon right tonsil, conjunctivitis, increasing tinnitus and deafness, injection of diphtheria antitoxin serum; a few hours later, total deafness with slight vertigo, great chemosis; gradual defervescence completed by the 13th day, at which date there was partial paralysis of accommodation together with paresis of extensor muscles of the head, persistent tinnitus, slight vertigo and absolute persistent loss of hearing. A married woman, aged thirty-three, came to him with sore throat, high fever, weakness and collapse. He found a suspicious looking eruption in the throat; she later had albuminuria and then membranous colitis. He could find no syphilis and no evidence of septic poisoning. She suddenly lost all power of hearing without any apparent cause; it was not like the deafness following mumps, meningitis or any other such trouble; he thought it was a disease of the labyrinth. He gave antitoxin because it looked like diphtheria, although several examinations failed to find the organisms. The deafness continued in spite of all treatment. He thought this was a very rare trouble.

DR. BEVERLY ROBINSON, of New York, said this

was a very interesting and unique case. It was also interesting from the standpoint of several cases which he related, and in which the diphtheria organisms could not be found, though the clinical picture was one of diphtheria. While it is gratifying to know from the Board of Health that these cases of his were not diphtheria, still he told the parents of the patients that it was diphtheria, and treated it as such. We should give some attention to the clinical side of the cases rather than too much to the bacteriological report of one who has never seen the case.

DR. I. E. ATKINSON, of Baltimore, said that such cases as Dr. Wilson had reported should be very carefully looked into to see that all the conditions of a careful diagnosis are fulfilled. In this case the diphtheria organism was wanting; but could we not account for these symptoms in another way? There may be some form of septic meningitis or an inflammation of the brain, just as in the deafness which comes from cerebro-spinal meningitis.

DR. M. H. FUSSELL, of Philadelphia, reported a case of deafness similar to Dr. Wilson's case.

DR. W. W. JOHNSTON, of Washington, thought that these might be anomalous cases, many of which are seen in a disease affecting many different parts of the body, that is, epidemic influenza. Possibly Dr. Wilson's case was of that kind. We all know how profoundly the nervous system is affected in this disease.

DR. WILSON said, in conclusion, that he had also seen his share of cases of epidemic influenza, and was rather well acquainted with the disease in all its forms. He thinks there is no link missing in the demonstration of this case. It does not seem worth while to go out of one's way to make a diagnosis. He had been very careful to use germicide, and had isolated the patient. He removed every one else, and no one saw the patient but himself and the nurse. He had never seen a case of this kind before. He agreed entirely with what Dr. Robinson said.

DR. J. P. CROZER GRIFFITH read a paper on

TYPES OF EDEMA IN INFANCY AND EARLY CHILDHOOD.

He discussed the obscurity which attends many cases of edema occurring at this time of life. He referred first to the possibility of nephritis being present in earliest infancy, and then took up the question of the production of congenital syphilis. He reported two cases as apparent proof of the occurrence of this form of renal disease, and referred to some instances from medical literature. The existence of nephritis in an infant as one manifestation of general septic infection was instanced by the report of a case. Edema consecutive to heart disease and to marasmic conditions was then touched upon, and then that under the name of edema neonatorum. The relation of this condition to sclerema neonatorum was next considered, and an instance of the latter reported. He then reviewed the cases of sclerema occurring in America. Next, angioneurotic edema, as seen in infants and children, was reviewed, and the various reported cases abstracted. He reported two instances occurring in his own experience. Finally, instances of edema of entirely doubtful origin were taken up, and two unusual cases detailed. Dr. Griffith also showed some very beautiful normal and pathological specimens which were treated in such a way that the material colors were preserved.

DR. D. D. STEWART, of Philadelphia, presented

A FURTHER COMMUNICATION ON THE OCCURRENCE OF A HITHERTO UNDESCRIBED FORM OF CHRONIC NEPHRITIS, UNASSOCIATED WITH ALBUMINURIA.

This was a continuation of a paper which was published several years ago. He dealt with an unrecognized form of chronic nephritis with distinctive symptoms, in which albumin even in traces by the commonly employed tests was persistently absent from the urine, and yet uremic symptoms are common. Although unable to present the result of a necropsy on a personally observed case of this sort, a portion of a kidney removed from a case in life throws some light on the pathological condition present.

DR. H. A. HARE, of Philadelphia, made a report on A STUDY CONCERNING THE CUMULATIVE ACTION OF DIGITALIS.

He first referred to experiments which were made to test the effect of digitalis on the muscular structure of the heart. He took a number of small pigs as nearly alike in weight as possible, and put six in one pen and six in another, and to one set of pigs he gave digitalis until they were taking 15 drops three times a day. In a little while he noticed that the digitalis pigs were more developed than the others, they gained more in weight, and were more lively and showed a desire to jump out of the pen. After killing the pigs he found that the hearts had gained in weight and the muscular structure was much thicker. Was this the cumulative action of digitalis? It is a more or less sudden development of the regular action of the heart; the effect is cumulative. He quoted many authorities to support his point. He had addressed a series of questions to a number of physicians throughout this country and elsewhere, asking if they believed in the cumulative effect of digitalis, and what was their experience with it, and in what form digitalis was used. He received a variety of answers.

DR. I. E. ATKINSON, of Baltimore, believed in this cumulative action; and DR. SHATTUCK and DR. MUSSER denied it entirely.

DR. WM. OSLER, of Baltimore, thought that cumulative action was exceedingly rare. When a man only gives a few drugs he does not like to hear anything against his friends. He gives digitalis largely and with a free hand, and has never seen the cumulative action. We all know the digitalis pulse. The digitalis pulse of the wrist is not the same as the digitalis pulse of the heart; the heart may be 80 while the wrist is 40. In cases of chronic valvular disease of the heart he had given 10 minims of tincture of digitalis, three times a day, for three years. The cumulative action may occur, but it is so rare that it may be disregarded.

DR. E. G. JANEWAY, of New York, asked if we always attributed sudden death in the hospitals to the right cause. He had looked up the hospital records and had found in several cases of sudden death, where autopsies showed no sufficient lesions, that the patient had been taking digitalis, which caused a slow heart and a slow pulse. Some such sudden deaths are probably due to the drug and not to the disease. Sudden death in pneumonia may be due to the digitalis which is given in large doses, and he is sure that it has been the cause of death in Bright's disease.

DR. GEORGE WILKINS, of Montreal, has used it in many cases in which he observed the cumulative action, and he reported several cases.

DR. J. C. WILSON, of Philadelphia, said that sudden death may occur from other causes as well as from digitalis. He has never seen a cumulative effect, and never gave it in pneumonia as a routine measure. He does not give it in fever; it does no good, and interferes with digestion; he has given 15 minims, three times a day for three or four weeks, until it was contraindicated. He has two rules in giving this drug: to let the patient take it a certain number of days, then stop it in order to prevent the poisonous action, and he always uses the tincture in moderate doses.

DR. J. T. WHITTAKER, of Cincinnati, has had to stop its use when nausea followed. He often gave it at the crisis in pneumonia.

DR. CHAS. CARY, of Buffalo, has never seen any poisonous effects from it, and referred to a case that had taken five drops every three hours for six months, but never took more than six doses in a day; and there were no bad effects.

DR. H. A. HARE said, in conclusion, that Dr. Osler had proved just what he had not intended to prove. The heart-pulse of 80 and a wrist-pulse of 40 was to him evidence of the cumulative action. He wished to emphasize his statement that the effect was cumulative and not the drug. It is well to remember that different results may be obtained because it is so difficult to get tinctures of uniform strength.

THIRD DAY. — THURSDAY.

DR. R. T. EDES, of Jamaica Plain, Mass., read a paper on

THE RELATION OF NEURASTHENIC CONDITIONS TO THE GENERAL NUTRITION.

Gain in body-weight and improvement in neurasthenic symptoms usually go together, but there are enough exceptions to the rule to show that the nervous nutrition is something more than a mere sample of the general. The more symptoms approach in character the "fixed idea" of the insane the less amenable are they to the beneficial effect of mere somatic therapeutics. The blood color (Fleischl) of a considerable number of neurasthenic patients corresponds quite closely with that of the employes in the same institution. It was not possible to establish any correspondence between the degrees of anæmia and the intensity of nervous symptoms. Measurements of the excretion of uric acid afford no sufficient ground for supposing that neurasthenic symptoms depend in any way upon this substance. There may be such a thing as a chronic uric-acid headache, but the ordinary continued neurasthenic headache is not of this character. Indian determinations have not been numerous enough to be decisive, but do not seem to indicate that the poison consists in this substance or in those which may be transformed into it. If neurasthenia is a toxic condition, the poison has not yet been satisfactorily identified.

DR. JAS. J. PUTNAM, of Boston, said he could corroborate the statements of this paper; neurasthenic patients look pale and bloodless and yet have the normal amount of blood. The uric-acid theory is far from being settled. Haig's writings are attractive, but devoid of the critical spirit which one would look for in such an important subject; there are loopholes for error in every step. Changes of metabolism are effected by the nervous system; normal and pathological nervous activities are immediately connected with

changes of metabolism. When the subjects are so clearly connected it is hard to say which is the cause, or if there is simply a union of both causes.

DR. NORMAN BRIDGE, of Los Angeles, Cal., read a paper on

THE REFLEX NEUROSES OF THE ABDOMEN.

His paper was simply an attempt to set forth from a clinical standpoint the large number of these reflex neuroses, as symptoms found are frequently overlooked and sometimes confusing in diagnosis. These reflexes are hard to understand; they cause the patient annoyance and often suffering; and some simulate grave diseases and continue for years. A common neurosis is increased peristalsis, causing the passage of gas and diarrhea. A diarrhea of the colon is frequent, and it is hard to understand why it follows so closely each meal, when it is, of course, the result of the previous meal. This diarrhea is due to the reflex cause, and may be brought on by excitement, by emotion, by fever, causes which are extra-abdominal. Public speakers are often affected by it; surgeons who are about to operate; and, in one instance, a clergyman was forced to give up his vocation because of these reflex disturbances. He mentioned a case of a woman who had regularly borborygmi and pain in the top of the head, which was brought on by mental excitement. Another reflex neurosis is slight sciatic pain after a passage from the bowels. Another reflex is what is commonly called "growing pains," which come from an overloaded condition of the stomach and bowels. A free evacuation will often stop it. Then again, prurigo of the legs is another reflex, which has the same cause and may be cured by the same treatment. In addition to that, we have the rash or urticaria caused by the eating of crabs, fish, strawberries and such things. Asthma is in many cases a spasm of the muscular structure of the lungs from faults of digestion. Convulsions, especially in children, are caused by an overloaded stomach. Insomnia is often averted by an enema at bedtime.

DR. WELCH referred to urticaria as a reflex phenomenon and mentioned the work of Dr. Gilchrist in his laboratory, which was striking. A class of cases in which a slight scratch of the skin causes an eruption. He had cut out small pieces of the skin and found that in five minutes after the irritation there was the presence of serum and migrated leucocytes, and in fifteen minutes after the irritation there was a large collection of leucocytes around the point of irritation. There must be something outside that attracts leucocytes, but it is not yet clear what. The reflex phenomenon does not explain how this chemotaxis takes place.

DR. STOCKTON, of Buffalo, said there were two points in the paper to which he would like to refer: one was the post-prandial diarrhea, if he might call it by that name, which occurs with sufficient frequency and has a sufficiently regular pathological course to have a name of its own. This is not simply a hurried evacuation of the intestinal canal after a meal, but later there is gastric anacidity. Then, again, this diarrhea seems to have many other peculiarities. He has recorded a number of cases in which there was a striking error of refraction of the eye. He does not mean to say that this depends on the ocular error, but he thinks all the conditions are connected. The other point is a painful neurosis in which there seems to be

a descent of the organs in the abdomen, causing pain. Thus he has found that fixing a floating kidney in this condition will often bring about a cure.

DR. F. H. WILLIAMS, of Boston, demonstrated

THE RÖNTGEN RAYS IN THORACIC DISEASES.

He referred to the general physical, chemical and physiological principles involved in the use of these rays. He has examined about 400 cases of thoracic disease in the hospital, some of which had pneumonia, and he had no untoward effects from the rays. He usually had the patient brought on a stretcher and placed in a recumbent position with a Crookes tube beneath and the fluoreoscope above. In this way he had examined most of the cases mentioned. He found this especially useful in detecting any increase in the density of the lungs, and he was much struck with the different powers of resistance of the different substances. Thus air is more permeable by the light than water. In order to use this instrument intelligently one must be familiar with the normal appearance of the body when viewed with these rays. He showed a number of charts which demonstrated the significance of the diaphragm outlines with deep inspiration and deep expiration, and also showed some beautiful radiographs of pneumonia, consumption and like subjects. He had watched about 40 cases of pneumonia throughout the course of the disease, and in several noticed especially that the lungs did not become normal until a month after apparent cure. He also said that with the fluoreoscope he could see the heart pulsations, and he noticed that the movement of the heart was less at the apex and greater at the left side than near the base.

DR. REGINALD H. FITZ, of Boston, showed some

RADIOGRAPHS OF ANEURISMS.

DR. W. H. WELCH, of Baltimore, then introduced DR. OSBORNE, of the New Haven Medical School, who reported a most interesting

CASE OF ACROMEGALY

in a man, forty-seven years old, who came to the New Haven Hospital complaining first of edema of the lower extremities. A complete history could not be obtained, but it was found that he had had the disease twenty-three years. He suffered also with tinnitus aurium, which is one of the early symptoms of this trouble. The man eventually died, and a post-mortem was obtained. A number of photographs of the case and of his hands and feet were shown, also specimens from his skeleton, which were especially characteristic, such as the lower jaw, the spinal column, the clavicles, and the phalanges of the fingers. He found that many of the organs were not only increased in size, but some were heavier than normal, especially the heart, which weighed two pounds and nine ounces, which is probably the heaviest heart on record. He thought the man also had a myxedematous complication. The pituitary body was affected as is usual in these cases. The thanks of the Association were extended to Dr. Osborne for this interesting case.

DR. JOHN J. ABEL, of Baltimore, discussed

THE CHEMICAL PROPERTIES OF THE BLOOD-PRESSURE-RAISING CONSTITUENT OF THE SUPRARENAL CAPSULE.

He thought that the suprarenal capsule was an organ of vital importance; it furnished to the blood

and to the muscular system a stimulant the nature of which could not exactly be made out. He had studied the subject very carefully, and had obtained a substance from the suprarenal capsule which had a stimulative effect; but in spite of all the work that had been done by chemists, there is still an uncertainty as to the nature of this substance.

DR. WM. OSLER, of Baltimore, asked if he had examined the commercial products of the market to see if this blood-raising product could be obtained. He had on hand now several cases of Addison's disease, and had seen no marked effect from the use of the suprarenal capsules.

DR. ABEL said he had not looked for a commercial product, but he thought it was very likely that one could be obtained, for it was a very simple matter to take the suprarenal capsules from sheep and dry them and reduce them to powder.

DR. SIMON FLEXNER, of Baltimore, read a paper on
THE OCCURRENCE OF THE FAT-SPLITTING FERMENT
IN PERITONEAL FAT NECROSES.

Upon the etiology of peritoneal fat necroses much light has recently been shed, partly through the findings in cases occurring in human beings and partly through animal experimentation. A study of the cases in the literature would make it appear that the occurrence of fat necroses was not always due to the same cause. Although infection seems in certain cases to play a part, it is probable that it is not by any means the most important factor. The view has gained ground that the disseminated forms of necroses met with in the peritoneal cavity, as well as the more circumscribed lesions in the pancreas itself, may result from a perversion of the pancreatic secretion.

Again, since it has been shown that trypsin when injected into the peritoneal cavity does not set up this condition, the suggestion that the fat-splitting constituent of the secretion, steapsin, might possibly prove to be the chief cause, has been ventured. In the literature no record occurs of any attempt to demonstrate the presence of this body in the areas of necrosis, and it is possible that investigators were deterred by the belief in its extreme sensitiveness. A suitable human case having presented itself, he undertook to prove the presence of this body in the fat necrosis and its absence from the normal fat. A satisfactory demonstration of this point having been arrived at, he next instituted a series of experiments in order to study more particularly the conditions under which the necroses make their appearance and the length of time the ferment is demonstrable in them. From the report of this experience he drew these conclusions:

- (1) In peritoneal fat necroses the fat is easily demonstrable.
- (2) It is present in the early stages, and may disappear later.
- (3) The ferment is the direct cause, which can be proved.
- (4) The escape of pancreatic secretion is the origin of the necroses.

He also showed some specimens under the microscope.

DR. W. H. WELCH, of Baltimore, said that some years ago he had brought a case before the Association, in which the micro-organisms were present. It was the first demonstration of the colon bacillus. He remembered that he had said at the time that he be-

lieved that the organisms had nothing to do with the necroses, and now this has proved to be true. It is very satisfactory to have these observations so well confirmed by Dr. Flexner.

DR. A. C. ABBOTT, of Philadelphia, read a paper on

FURTHER STUDIES UPON THE PATHOGENIC SPIRILLA
OF THE SCHUYLKILL RIVER AT PHILADELPHIA.

This was the result of further experimental work by himself and Dr. D. H. Bergey. They had examined the Schuylkill water, and found certain spirilla which seemed to be present all the year round. He had only found them in the Schuylkill and the Delaware. He could not examine the water from other rivers, but he believed this was due to some contamination. He found 110 varieties of organisms, but they had so many points of difference and overlapped each other in so many ways that a classification was almost impossible. Even the division into the pathogenic and non-pathogenic was hardly satisfactory, as some of the pathogenic organisms were very weak, while some of the non-pathogenic organisms seemed to respond in every other way to the test of the pathogenic organism. They expected still to continue this work.

SURGEON-GENERAL GEO. M. STERNBERG thought these observations made at this time when there was no cholera in the country were exceedingly valuable. If he had found these spirilla at the time when the cholera was suspected or was present they would certainly have been called cholera organisms.

DR. B. MEADE BOLTON, read a paper entitled
THE EFFECTS OF VARIOUS METALS AND METALLIC
SALTS ON THE GROWTH OF CERTAIN BACTERIA.

This was the result of original work done by himself and Dr. W. G. Brown. They found that the zones that are formed by bacteria around bits of metal laid on plate cultures are due to the fact that the solution of the metal tends to concentrate in one or more zones. Where the concentrated zone of the metal is formed the bacteria fail to grow. Metallic salts act in the same manner as the metals. The more soluble the salt the more pronounced the action. In the zones where the growth is more pronounced than on other parts of the plate the colonies are usually fewer but larger in size.

DR. WALTER REED, of Washington, read a very elaborate paper on

THE APPEARANCE OF CERTAIN AMEBÆ-LIKE BODIES
IN THE BLOOD OF VACCINATED MONKEYS (RHOESUS)
AND CHILDREN, AND IN THE BLOOD OF VARIOLA:
AN EXPERIMENTAL STUDY.

Following the introduction of Koch's improved methods, the search for the specific causative agent of vaccinia has been made especially along the line of bacteriological research. Notwithstanding many claims of positive results, these have in the end proved groundless. During the past ten years, and more especially during the last half-decade, the attention of investigators has been turned toward the possibility of the animal nature of the parasite. Van Der Loeff, L. Pfeiffer, Rieck and more recently, Ogata, have described minute bodies always present in vaccine and variolous lymph, which they assign to the sporozoa. The first attempt to cultivate the supposed parasite of vaccine lymph was made in 1892 by Guarneri, who

used the cornea of guinea-pigs and rabbits for this purpose. After forty-eight hours, epithelial scrapings from the inoculated cornea, suspended in a hanging drop of aqueous humor, showed little shining, slowly moving ameboid bodies, often with irregular margins, within the epithelial cells. Guarnieri considers these bodies to belong to protozoa, and calls the parasite *citrocytes vaccinia*. These observations have been confirmed by L. Pfeiffer, Von Sicherer, Clark and E. Pfeiffer. Ferroni and Massari have failed to confirm Guarnieri's observations. In 1894, L. Pfeiffer reported the finding in the blood of vaccinated children (seventh day), and calves (fourth day), and in the blood of variola ameboid cells (provided with pseudopodia) one-half the size (in the calf) of a red cell, and (in the child) one-fourth the size of a red cell. These bodies are not intracellular, but swim free in the blood. They have a nucleus; and sometimes flagella — which can be stained — appear during the stage of fever, and disappear. My own experiments confirm in some respects Pfeiffer's observations. Bodies of a corresponding size, and ameboid in character, appear in the blood of vaccinated monkeys about the seventh and disappear about the twelfth day. The same bodies are found in the blood of vaccinated negro children, but were much more difficult to find in the blood of white children, and in several cases of the latter could not be discovered. Bodies of a like nature, though differing somewhat, were found in the blood of three small-pox patients during the height of fever, disappearing later.

DR. F. H. WILLIAMS, of Boston, then gave an account of

AN EPIDEMIC OF CEREBRO-SPINAL MENINGITIS CAUSED BY DIPLOCOCCUS INTRACELLULARIS MENINGITIDIS (JAEGER).

He said that there had been a slight epidemic of cerebro-spinal meningitis in Boston, and the opportunity had been taken to examine the cerebro-spinal fluid obtained by a puncture at the level of the second lumbar vertebra. He described the epidemic and gave a brief outline of the treatment.

The pathological results in these cases were reported by Dr. W. T. Councilman, of Boston, who began by quoting the observations of Weichselbaum who first found the organisms in cerebro-spinal fluid. This trouble sometimes came from acute otitis media. He found staphylococci, streptococci and diplococci. He had 11 cases in all in which these organisms were found by cultures from the fluid obtained. He found organisms in nine cases out of 20 at the City Hospital, and in 16 out of 30 at the Children's Hospital. In some cases the spleen was enlarged. These organisms have sometimes been found in the nasal sinuses and in one case in an abscess of the tonsil. The organisms grow best on blood serum.

DR. GUITERAS had seen two cases, which he would relate more fully later. One was in a hospital nurse and one was in a new-born child. The organism was found in the blood. There was no other lesion.

DR. WILLIAMS said that the lumbar puncture was of great value in the diagnosis, but the relief to the symptoms was only temporary. The fluid should be withdrawn gradually, 70 per cent. of the cases died.

DR. COUNCILMAN referred to the character of the exudation, and said that in quite a number it had a tendency to extend along the cranial nerves; in one case along the optic nerve so that it could be seen

with the naked eye, and that in some cases which had recovered there had been loss of sight and hearing. The eye complications will be found to be due to infection directly from the meningitis.

DR. F. C. SHATTUCK has seen about 15 cases, and his experience has been that not a child had died and not an adult had recovered.

DR. A. A. SMITH, of New York, reported a case of
LEVANT FEVER.

This fever has many names, but the one he selected seems to be the most suitable. It is a disease which exists especially on the eastern shores of the Mediterranean Sea. His patient was a woman from Bayront who was the wife of a physician who had seen many cases, and he had given Dr. Smith a careful description of these cases. This patient was first seen in January, 1897, and had been sick only since July, 1896. The fever would continue for three or four weeks; then it would cease; then there would be a relapse, which was often more severe; and then especially there would be intervals of freedom from fever. In her case the fever still continued. It seems to change its character often. It resists quinine. He examined the blood very carefully, and showed some beautiful specimens which were unpigmented. There is no pigment in the blood plasma nor in the blood corpuscles. The parasite which he described was much like Laveran's organism, but contained no pigment.

In answer to Dr. Shattuck he said that arsenic had been used, and indeed everything except phenic acid.

DR. GEORGE DOCK, of Ann Arbor, said that these specimens and this description would make one think of the form of malarial parasite without pigment which had been described by the Italian writers. Lack of pigmentation and segmentation would seem to do away with resemblance to the usual malarial parasites. We do find in fevers certain bodies which look like the malarial parasite; and when Laveran's observations were first published writers in Germany and elsewhere said they could find these bodies in other diseases. They looked too much like protozoa. The appearance of the colored drawings made him very sceptical. We should be very slow to believe that the parasite of Levant fevers has been discovered.

DR. A. JACOBI, of New York, read by title a report of

A CASE OF ADENOMA OF THE LIVER WITH COMPLICATIONS.

DR. B. K. RACHFORD, of Cincinnati, then spoke of
THE TREATMENT OF LITHEMIA

and called special attention to the following prescriptions, which were put up in siphons and charged with carbon dioxide.

One siphon contained:

R Sod. sulphate, 120 grs. wet salt.
Sod. phosphate, 30 grs. wet salt.
Sod. salicylate from oil wintergreen, 10 grs.
Tr. nux vomica, grt. 3.
Aqua, q. s. 3 iv., CO₂ q. s.
Take before breakfast.

The other contained:

R Sod. sulphate, 30 grs. dry salt.
Sod. salicylate from oil wintergreen, 10 grs.
Magnesia sulphate, 50 grs. wet salt.
Benz. lithia, 5 grs.
Tr. nux vomica, grt. 3.
Aqua, q. s. 3 iv., CO₂ q. s.
Take before breakfast.

DR. JAS. T. WHITTAKER, of Cincinnati, read a paper on the

EARLIEST POSSIBLE RECOGNITION OF TUBERCULOSIS.

Physical symptoms do not always show the beginning of tuberculosis, and the bacilli sometimes escape observations. The approach of the disease is very insidious. The symptoms may look suspicious, but it is very important to make early the exact diagnosis; and he would like to emphasize more thoroughly the great value of tuberculin in the early diagnosis of tuberculosis. The use of tuberculin was objected to on the score that it caused a reaction when there was no tuberculosis. This is hardly true. In the first test five millimetres of tuberculin should be used, and so on up to two centigrammes. There should be no reaction if tuberculosis is not present. Virchow raised an objection against tuberculin because he said it aroused latent tuberculosis and caused the disease to be spread throughout the whole body. It must be remembered that tuberculin should not be used in too large doses or too late in the course of the disease.

DR. F. C. SHATTUCK said that tuberculin had been used in his hospital, and no harm had come from it. If tuberculin were used regularly the number of cases would be increased, but there would be more recoveries.

DR. A. L. MASON, of Boston, said that tuberculin had been used a good deal in the Boston City Hospital, and said that it had often been the means of deciding whether to do a laparotomy or not when depending on the presence or not of tuberculous peritonitis.

DR. E. A. DESCHWEINITZ, of Washington, read a paper on

SOME PRODUCTS OF THE TUBERCULOSIS BACILLUS AND THE TREATMENT OF EXPERIMENTAL TUBERCULOSIS BY ANTITOXIC SERUM.

He gave a description of two of the products obtained from tuberculosis cultures; one of these a crystallizable acid, and its probable bearing upon the progress of the disease. A brief sketch of some experiments showing the relationship of the attenuated tuberculosis bacillus to immunity was given, followed by a description of some methods for the production of antitoxic serum and its experimental application. He used injections of live cultures, which he found to be the best. Horses are better than other animals to use. At no time has he produced toxic effects, but care must be exercised to prevent any dangerous results.

DR. D. D. STEWART, of Philadelphia, read a paper on

THE OCCURRENCE OF PRIMARY RENAL TUBERCULOSIS,

which was the result of some work by himself and Dr. A. D. J. Kelley, of Philadelphia. The diagnosis, frequency of occurrence, and source of infection of tuberculosis of the kidney as a primary affection was discussed; and an unreported case of Dr. Stewart's in which a limited, primary tuberculosis of the pelvis of the left kidney occurred in a case of chronic nephritis was reported.

DR. H. A. HARE of Philadelphia, reported

A FURTHER STUDY ON SOME OF THE UNTOWARD EFFECTS OF THE BROMIDES.

This paper was a study of the frequency with which this class of drugs produced evil influences and the manner in which these results were obtained. He re-

ferred to Dr. Weir Mitchell of last year, and said that before he looked into the matter he thought that Dr. Weir Mitchell's work was original, but on inquiring from the asylum superintendents he found the subject was an old one and well known. He looked up the literature on the subject, and found that much had been written on it. He addressed a series of questions to various asylum physicians, and the general answers seemed to be that most of them had seen attacks of maniacal delirium following the excessive use of the bromides, especially in epilepsy; so that patients have nerve storms in which they have homicidal or suicidal mania. He thought that the presence of potassium in bromide of potassium caused a certain amount of poisoning, and therefore he preferred the sodium salts.

DR. H. C. WOOD, of Philadelphia, thought that a great deal of what asylum physicians and superintendents reported rested on an insignificant basis. A man for instance has epilepsy, bromides are given him; bromides do not cause the mania, but at times the attacks take another direction. He preferred the ammonium bromide to the sodium, and referred to a quack in New York who always used the ammonium salts, and that he had done a great deal of good to a patient whom Dr. Weir Mitchell had not helped at all. He found out what the quack was giving by analyzing a bottle of the medicine.

DR. I. E. ATKINSON, of Baltimore, thought that bromide of potassium was so much used that these untoward effects represented by Dr. Hare would have been observed before. It must be in part an idiosyncrasy.

DR. HARE reported in conclusion that many hospital physicians had told him that they hoped he would impress upon the general profession not to give so much of the bromides, because cases which entered asylums under the influence of the bromides were torpid and stupid and had to be freed from the effects of the bromides.

At the business meeting on the morning of the first day, the recommendation of the Council for the adoption of the amendment increasing the limit of membership from 100 to 125, which was offered last year, was acted upon favorably by the Association.

Dr. Frederick C. Shattuck, of Boston, was elected President; Dr. G. Baumgarten, of St. Louis, Vice-President; Dr. M. Allen Starr, of New York, Councillor; Dr. J. T. Whittaker, of Cincinnati, Alternate Representative to the Congress.

The second week in May, at Washington, was named as the time and place of the next meeting.

"THE MOST PAINFUL OPERATION KNOWN TO SURGICAL SCIENCE." — A correspondent of the *London Daily Telegraph*, in describing a visit to the military hospital at Larissa, gave the following harrowing account of what he saw there: "The medical department," he says, "did its best under the unfavorable conditions. Operations, however, had to be performed without the administration of narcotics. Thus one man, whose face had been horribly disfigured by bombs, underwent the most painful operation known to surgical science — that is, the cutting out of both optical nerves — without the aid of anesthetics. This man was a German, and his exquisite suffering painfully impressed me."

THE BOSTON
Medical and Surgical Journal.

THURSDAY, MAY 20, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DANRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE CHEMISTRY AND PATHOLOGY OF GOUT

THE Goulstonian lectures on "The Chemistry and Pathology of Gout,"¹ by Arthur P. Luff, are of unusual interest. Dr. Luff has performed many experiments to determine the seats of formation of uric acid in the economy, and the presence or absence of uric acid in the blood in normal and morbid states, also laboratory experiments with solutions of sodium urate, and it is these original researches which give the chief importance to these lectures.

The main points and conclusions arrived at in these lectures are as follows:

(1) Uric acid is not normally present in the blood of man and other mammals nor in the blood of birds. This proposition is based on a great number of careful experiments made by Von Jaksch, Klemperer, and the author of these lectures; the latter regards the fact as established beyond question.

(2) Uric acid is produced normally only in the kidneys.

This, according to Dr. Luff, was the accepted belief down to 1847. Till that time, no uric acid had been detected in the blood. In 1847, Garrod showed the presence of uric acid in the blood of gouty persons, which led to the view that it was formed in other organs and tissues of the body and excreted by the kidneys. Garrod, who originally held this view, subsequently came to believe that uric acid was produced by direct action of the kidneys from urea and other nitrogenized bodies in the blood. Hence the presence of this acid in the blood implies its absorption from the kidneys. Kalisch and Latham also regard the kidneys as the chief uric acid formers, through conjugation of substances formed in the liver. Zalesky's experiments on serpents also favored this doctrine, no uratic deposits being found in any of the tissues after removal of the kidneys. The views of Charcot and Murchison as to uric acid being formed in the liver are regarded by Dr. Luff as erroneous, and based on theoretical considerations only.

¹ Lancet, March 27, April 3, 17, 1897.

(3) Uric acid is normally formed from urea, probably by conjugation of that substance with glycocine in the kidneys.

Glycocine is a derivative of biliary acids, and having served its purpose, is probably converted, with other amido-bodies — taurin, leucin, and tyrosin, into urea in the hepatic cells. The considerations given by Latham (Croonian Lectures, 1892) whereby this view of the production of urea is probable are too lengthy and intricate to be dwelt on here — that glycocine is concerned in the production of uric acid may be inferred from the fact that in the carnivora whose urine contains little or no uric acid the bile contains no glycocholic, but only taurocholic acid, and therefore yields no glycocine.

The proposition that the kidneys form uric acid out of urea is only an inference from facts such as this, that no uric acid is found in the blood of the renal artery going to the kidney, but only urea, and from analyses of the blood and urinary excrement of birds.

If uric acid be formed in the kidneys from urea and glycocine, brought from the liver, it can be readily understood that alterations in the metabolism of the liver must affect the formation and excretion of uric acid. This would explain why liver trouble of some kind is so commonly associated with gouty dyspepsia. Harley and other authorities have always held that a strong relationship exists between gout and hepatic derangements.

(4) Uric acid is present in the blood in gout as a soluble sodium quadriurate. Investigations have shown that the amorphous deposits in acid febrile urines consist of quadriurates of the three alkalies, sodium, potassium and ammonium, and it would seem that the uric acid which is formed in the kidneys is at once converted into the mixture of these quadriurates, which in the normal state are excreted, dissolved in the urine. If, however, any absorption of these takes place into the blood, as probably occurs in the gouty state, the ammonium and potassium quadriurates would be converted by the sodium carbonate of the blood into sodium quadriurate which would constitute the sole compound of uric acid circulating in the blood.

In its soluble form, this quadriurate is not a toxic agent. This is proved by the presence in excess of urates in leucocythemia and states of anemia generally where this excess *per se* is not baneful. The urates of the blood are deposited in the joints, etc., as sodium biurate, which acts passively and physically as a foreign body and irritates the parts where deposited.

(5) The presence of uric acid in the blood in gout is due to its deficient excretion by the kidneys, and to the subsequent absorption of the non-excreted portion into the blood from those organs.

This is in accordance with the view of the older authorities, notably Garrod, Sir William Roberts, Levison, also of Von Jaksch, Klemperer and others.

(6) Gout is always preceded by some affection of the kidneys, functional or organic, which interferes with the proper excretion of uric acid.

Here again, there is a notable consensus of many authorities, Dr. Norman Moore, who bases his observations on a large number of post-mortem examinations, states that chronic interstitial nephritis is found in a large proportion of those bodies in which sodium urate is to be seen in the joints. Levison is a strong supporter of the view that there is always some degree of antecedent renal disease connected with gout and he thinks that the exceptional cases adduced by some authors are open to criticism. Luff's seventy-seven examinations of chronic gouty patients revealed in all granular kidney disease.

Luff states, as the result of his studies, that the probable seat of the kidney affection giving rise to gout is the epithelium of the convoluted tubes.

(7) In certain diseases of the blood, and disorders accompanied by leucocytosis, uric acid is formed within the system from nuclein and impregnates the blood.

This statement is based chiefly on experiments by Horbaczewski and Umber. The view of the former is that sudden variations in uric-acid production may be due to the breaking up of leucocytes and conversion of their nuclein into uric acid within the system. In leucocytosis, the excess of uric acid thus formed is rapidly excreted in the urine.

(8) The solubility of uric acid in the blood is not affected by a diminished alkalinity of the blood produced by the addition of organic acids.

This proposition is based on careful experiments on blood serum charged with urates—not in the living organism, but in the chemical laboratory. These are, of course, open to the objection that processes under the control of the vital forces cannot be exactly imitated out of the body. If valid, they teach that the ingestion of vegetable acids is not harmful in gout.

(9) The deposition of sodium biurate is not accelerated by a diminution of the alkalinity of the blood.

This is also the result of experiments *in vitro*. If this proposition be correct, the ingestion of alkalies can have little remedial effect in gout.

(10) An increased alkalinity of the blood does not increase the solubility of deposits of sodium biurate.

This statement is also based on laboratory experiments. The therapeutic inference is the same as in Proposition 9. It runs counter to much current theory and practice.

Another series of experiments performed by Luff on solutions of quadriurates out of the body are in confirmation of empirical notions long held, namely, that the saline constituents of vegetables exercise a remarkable inhibitory power over the decomposition of sodium quadriurate. In other words, a vegetable diet promotes the solution in the system and inhibits the deposition of urates. If this deduction be sound, it is a therapeutic rule of the utmost importance for the gouty.

He also states as conclusions from similar experiments that the solubility of sodium urate in the blood is diminished by the presence of the saline constituents of meat. This, again, is in conformity with old tradi-

tional and empirical notions, and gives a sanction to the rigid exclusion of animal food from the diet of the gouty.

MEDICAL NOTES.

THE INTERNATIONAL CONGRESS AT MOSCOW. — Dr. Lauder Brunton has accepted an invitation to deliver one of the general addresses before the Congress at Moscow.

DENVER AND THE AMERICAN MEDICAL ASSOCIATION. — The medical profession of Denver, Col., have decided to extend to the American Medical Association, at their coming meeting in Philadelphia, an invitation to meet in Denver in 1898.

THE ADVANTAGES OF TECHNICAL LANGUAGE. — The advantages accruing to the modern trained nurse from a familiarity with technical medical terms are shown by the recent remark of a nurse in attendance upon a man suffering from vesical retention. The patient had for some days been obliged to make several futile attempts in each case before accomplishing the function of micturition. Finally relief came, and the nurse saluted the doctor at his morning visit with the cheerful words, "He passed water to-day *by the first intention*."

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, May 19, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 84, scarlet fever 98, typhoid fever 14, small-pox 3.

PUBLIC CHARITABLE AND REFORMATORY INSTITUTIONS OF MASSACHUSETTS. — The Massachusetts Legislature has voted to refer to the next General Court the recommendations of the report of the Commission appointed by the Governor of the Commonwealth to investigate the public charitable and reformatory interests and institutions of the State.

THE MASSACHUSETTS SCHOOL FOR THE FEEBLE-MINDED. — The trustees of this institution in their report for the year ending September 30, 1896, give the following statements of its work: "There are now in the school 425 inmates, feeble-minded persons of all descriptions. Of these, 181 are supported by the Commonwealth in the school department and 37 in the custodial department. The towns and cities are charged for the support of 155 in the custodial department. There are 34 private pupils, of whom 5 pay more than the average cost of maintenance and instruction, 12 pay the average cost of maintenance and instruction and 8 pay about one-half the average cost. There are 27 beneficiaries of other States, who pay each about \$300 per year. The average number for the year has been: males, 248; females, 168; total, 416. There have been 164 applications for admission, but of these only 22 could be received. The

current expenses for the year have amounted to \$70,-761.98, or \$3.25 per week for each inmate."

NEW YORK.

BUILDINGS FOR THE CONSOLIDATED MEDICAL SCHOOLS.—At a meeting of the corporation of the University of the City of New York held May 14th, the committee having in charge the consolidation of Bellevue Hospital Medical College with the medical department of the University made an elaborate report, which was unanimously adopted. Plans for the proposed new buildings were submitted, together with diagrams showing their relative positions. These, with the old buildings of the University School, enlarged and improved, the Loomis Laboratory, the Carnegie Laboratory, and the schools for male and female nurses, will take up almost the entire block located between 25th and 26th Streets and First Avenue and the East River; while the old Bellevue College building within the grounds of Bellevue Hospital, across the street, which was partially destroyed by fire during the past winter, will be used as a dispensary for out-patients.

THE FACULTY OF THE NEW MEDICAL SCHOOL.—The work of arranging the Faculty and various teachers of this great consolidated medical school was one of much delicacy. It was unanimously agreed that the University corporation should elect the new Faculty, and in order that there might be as little embarrassment as possible the members of the old ones all tendered their resignations. The corporation then furnished blanks to the professors, and asked them to nominate men whom they considered most competent to fill the different chairs, and it is stated that the corporation selected nine-tenths of those who were thus recommended. While there were twenty professorships in the former medical department of the University, there are now forty-one in the new consolidated school. The following is a list of those elected:

PROFESSORS.—Medical Ethics, Dr. John P. Munn; Pathology, Dr. J. G. Adami; Public Medicine and Infectious Diseases, Dr. Hermann M. Biggs (Bellevue); Applied Anatomy and Clinical Surgery, Dr. Joseph D. Bryant (Belv.); Physiology, Dr. Austin Flint (Belv.); Practical Anatomy, Dr. Irving S. Haynes (University); Materia Medica and Therapeutics, Dr. Henry P. Loomis (Univ.); Obstetrics, Dr. Wm. T. Lusk (Belv.); Gynecology, Dr. Wm. M. Polk (Univ.); Theory and Practice of Medicine, Drs. A. Alexander Smith (Belv.) and W. Gilman Thompson (Univ.); Surgery, Dr. Lewis A. Stimson (Univ.); Chemistry, Physics and Toxicology, Dr. Rudolph A. Witthaus (Univ.); Anatomy, Dr. George Woolsey (Univ.).

EMERITUS PROFESSORS.—Chemistry, Dr. R. Ogden Doremus (Belv.); Medical Jurisprudence and Psychological Medicine, Dr. Alexander E. Macdonald (Univ.); Otology, Dr. Chas. I. Pardee (Univ.); Orthopedic Surgery, Dr. Louis A. Sayre (Belv.); Materia Medica and Therapeutics, Dr. William H. Thomson (Univ.); Dermatology, Dr. Henry G. Piffard.

ADJUNCT AND ASSISTANT PROFESSORS.—Obstetrics, Dr. J. Clifton Edgar (Univ.); Practical Anatomy, Dr. John F. Erdmann (Belv.); Surgery, Dr. Frederick W. Gwyer (Univ.); Medicine, Dr. Egbert LeFevre (Univ.); Chemistry, Dr. J. A. Mandel (Belv.); Anatomy, Dr. George D. Stewart (Belv.); Chemistry and Physics, Dr. Ivan Sickels (Univ.).

CLINICAL AND SPECIAL PROFESSORS.—Otology, Drs. Edward B. Dench (Belv.), and Gorham Bacon; Diseases of the Nose and Throat, Drs. F. H. Bosworth (Belv.), and Cornelius

G. Coakley (Univ.); Ophthalmology, Drs. Charles S. Bull (Univ.), and Henry D. Noyes (Belv.); Surgery, Dr. Frederic S. Dennis (Belv.); Diseases of the Nervous System, Dr. Edward D. Fisher (Univ.); Genito-Urinary Diseases, Drs. Samuel Alexander (Belv.), and P. A. Morrow (Univ.); Midwifery, Dr. Austin Flint, Jr. (Belv.); Dermatology, Dr. John A. Fordyce (Belv.); Mental Diseases, Dr. Carlos F. MacDonald (Belv.); Diseases of Children, Drs. Wm. P. Northrup (Belv.), and Joseph E. Winters (Univ.); Medicine, Drs. Beverley Robinson (Belv.), and Charles E. Quimby; Lecturer on Orthopedic Surgery, Dr. Reginald H. Sayre.

In the above list there appear the names of but two who did not formerly occupy positions in either Bellevue or the University Medical School, namely, Drs. John P. Munn and J. G. Adami. Dr. Munn is the only member of the Faculty who is also a member of the Council of the University. Dr. Adami is now Professor of Pathology in McGill University, Montreal, and has an international reputation. He is a graduate of Cambridge University, where he formerly held an assistant professorship. It is also announced that Dr. Edward G. Janeway, who preceded the late Dr. Austin Flint in the Chair of Practice of Medicine in the Bellevue Hospital Medical College, but resigned the position some years ago, will be one of the professors in the new Faculty and will give a special course of lectures upon some topic not yet fully determined upon. The chairs of histology and bacteriology have not been filled, and no appointments to them will be made until Dr. Adami's arrival in New York. Dr. Munn is to be Dean, and Dr. Egbert LeFevre, Secretary of the Faculty. Up to the previous time Dr. W. T. Lusk has been President, and Dr. Austin Flint, Secretary of the Bellevue School, and Dr. C. I. Pardee, Dean of the University Medical School.

THE MORTALITY RATE DIMINISHES.—There has of late been a notable diminution in the mortality of the city. During the week ending May 8th there were reported 770 deaths against 815 in the previous week, and in the week ending May 15th, the number was reduced to 709. The decrease is especially marked in the mortality from pneumonia and tuberculosis, the deaths from the latter declining from 106 in the week ending May 8th to 62 in the week following. As the season advances influenza is on the wane, the number of deaths decreasing from 11 to 4. Small-pox also seems to be disappearing, and in the last week but one death from it was reported.

Miscellaneous.

ANTIVISECTION IN THE DISTRICT OF COLUMBIA.

IN connection with the receipt of Public Document 31, Part 2, which is entitled a "Second Memorial from a Joint Committee of the Medical and Other Scientific Societies and Educational Institutions of the District of Columbia, protesting against the Proposed Legislation Embodied in Senate Bill, 1552, entitled 'A Bill for the Further Prevention of Cruelty to Animals in the District of Columbia,' and Presenting their Views on

the Same," we print the following extract from the *Congressional Record* of May 13, 1897:

PREVENTION OF CRUELTY TO ANIMALS.

Mr. Gallinger.—I am directed by the Committee on the District of Columbia, to whom was referred the bill (S. 1063) for the further prevention of cruelty to animals in the District of Columbia, to report it favorably without amendment, and submit a report thereon. I desire to enter a request that 500 additional copies of the bill be printed for the use of the Committee on the District of Columbia.

The Vice-President.—Is there any objection to the request made by the Senator from New Hampshire? The Chair hears none, and the order to print 500 additional copies will be made.

Mr. Gallinger.—In connection with the report submitted a moment ago, I desire to give notice that I shall endeavor to have the bill called up for consideration at a very early day. A favorable report was made on a similar bill during the first Session of the Fifty-fourth Congress, but in deference to the wishes of Senators I did not press it for consideration. It is a matter of great importance, and I simply desire now to give notice, so that the Senate may understand it, that I shall endeavor to get early consideration for the bill.

The Vice-President.—The bill will be placed on the Calendar.

THE LATE DR. WILLIAM G. WHEELER.

RESOLUTIONS OF THE GYNECOLOGICAL SOCIETY OF BOSTON.

At a regular meeting of the Gynecological Society of Boston, held May 13, 1897, the following resolutions were unanimously adopted:

Resolved, That this Society learns with deep regret of the death of Dr. Wm. G. Wheeler, an honorary member, a former president, and one of its original founders.

Resolved, That our late comrade was not only distinguished for his great surgical skill, and for acute perception of the salient points of diagnosis, but also for exceptional kindness of heart and for untarnished honor. His interest in the Society's welfare continued to the last, notwithstanding advanced age and infirmities. We shall all miss his genial presence.

Resolved, That a copy of these Resolutions be sent to his family and also to the *Boston Medical and Surgical Journal*.

Obituary.

DR. W. B. CUSHMAN.

DR. WILLIAM B. CUSHMAN, of Oxford, Mass., whose death was noted in the *JOURNAL* of last week, was an able and successful practitioner, and a man who had in a high degree the confidence and respect of the community in which he practised.

He was born in Roxbury, Mass., in 1856. He graduated at the Roxbury Latin School, Harvard College and Harvard Medical School, after which he held the position of demonstrator of anatomy in the Bowdoin Medical School for a time. He began practice at Cumberland Mills, Me., after studying two years at the Eye and Ear Infirmary at Boston. He came to Oxford in 1880, soon won a reputation for skill and devotion in the treatment of his cases, and had been in the active exercise of his profession up to the time of his death.

It is reported that his last illness was brought on by overwork and exposure incident to his professional duties. He was a censor of the Massachusetts Medical Society. A widow and two sons survive him. During the hour of his funeral service all the stores in Oxford were closed, and business was suspended in his honor.

METEOROLOGICAL RECORD

For the week ending May 8th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Baro- meter	Thermom- eter.		Relative humidity.		Direction of wind.		Velocity of wind.		We'thr.		Rainfall in inches.

Deaths reported 3,202; under five years of age 1,045; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping cough, erysipelas, diarrheal diseases and fever) 349, acute lung diseases 489, consumption 387, diphtheria and croup 135, diarrheal diseases 60, typhoid fever 36, scarlet fever 30, cerebro-spinal meningitis 30, measles 26, whooping-cough 21, erysipelas 8, small-pox 3.

From scarlet fever New York 7, Philadelphia 6, Boston 5, Brooklyn 4, Chicago 3, St. Louis, Worcester, Brockton, Haverhill and Taunton 1 each. From cerebro-spinal meningitis Boston 13, Somerville 6, New York 5, Pittsburg and Malden 2 each, Cleveland and Worcester 1 each. From measles New York and Brooklyn 7 each, Chicago 5, Philadelphia 3, Pittsburg and Springfield 2 each. From whooping-cough New York 9, Philadelphia and Baltimore 3 each, Chicago and Cincinnati 2 each,

Boston and Washington 1 each. From erysipelas New York 4, Chicago, Baltimore, Boston and Providence 1 each. From small-pox New York 2, Somerville 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,982,524, for the week ending May 1st, the death-rate was 18.3. Deaths reported 3,854; acute diseases of the respiratory organs (London) 273, measles 110, whooping-cough 104, diphtheria 55, scarlet fever 32, diarrhoea 31, fever 19.

The death-rates ranged from 9.9 in West Ham to 28.9 in Salford; Birmingham 20.7, Bradford 16.2, Cardiff 13.8, Gateshead 15.5, Hull 21.8, Leeds 17.3, Liverpool 22.2, London 16.8, Manchester 25.2, Newcastle-on-Tyne 19.7, Nottingham 15.7, Plymouth 12.8, Sheffield 22.4.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 8, 1897, TO MAY 14, 1897.

Leave of absence for one month, with permission to apply for an extension of two months, is granted CAPTAIN R. K. BALL, assistant surgeon, U. S. Army, Fort Adams, R. I.

COLONEL WILLIAM H. FORWOOD, assistant surgeon-general, MAJOR LOUIS M. MAUS, surgeon, CAPTAIN RUDOLPH G. EBERT, assistant surgeon, are detailed to represent the Medical Department of the Army as delegates at the annual meeting of the American Medical Association, to be held in Philadelphia, Pa., June 1 to 4, 1897.

The leave of absence granted CAPTAIN NATHAN S. JARVIS, assistant surgeon, is extended to July 1, 1897, at which time his resignation has been accepted by the President to take effect.

FIRST-LIEUT. PAUL F. STRAUB, assistant surgeon, is assigned to duty with Troop C, 4th Cavalry, during the season at Sequoia National Park and General Grant National Park, California.

CAPTAIN MERITTE W. IRELAND, assistant surgeon, is assigned to duty with Troop K, 4th Cavalry, during the season at Yosemite National Park, California.

FIRST-LIEUT. GUY C. M. GODFREY, assistant surgeon, now on temporary duty at St. Paul, Minn., will proceed on the 15th instant to Fort Yellowstone, Wyo., and report to the commanding officer for temporary duty with troops in the National Park, during the season.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE WEEK ENDING MAY 8, 1897.

PROMOTION.

E. K. SPRAGUE, assistant surgeon, commissioned as passed assistant surgeon. May 7, 1897.

MASSACHUSETTS MEDICAL SOCIETY. ONE HUNDRED AND SIXTEENTH ANNIVERSARY.

The annual meeting will be held at 9 o'clock A. M., Wednesday, June 9, 1897, in the building of the Massachusetts Charitable Mechanic Association, on Huntington Avenue, Boston.

Meetings of Sections will be held in the same building, on the preceding day, Tuesday, June 8th.

TUESDAY, JUNE 8, 1897.

At 10 A. M., the Fellows of the Society are invited to visit the Massachusetts General Hospital on Blossom Street; the Boston City Hospital on Harrison Avenue; the Children's Hospital on Huntington Avenue, and the Carney Hospital, South Boston. The new Clinical Laboratories at both the Massachusetts General and the Boston City Hospitals will be open for inspection.

At 1 P. M., in Cotillion Hall, the Shattuck Lecture will be delivered by Dr. D. W. Cheever, of Boston; subject, "The New Surgery."

At 2.30 P. M., in Banquet Hall, meeting of the Section in Medicine. Dr. C. E. Stedman, of Dorchester, Chairman; Dr. G. G. Sears, of Boston, Secretary. General Subject, "Dyspepsia and Dietetics." Papers will be read as follows:

"General Remarks on Dyspepsia," by Dr. E. G. Cutler, of Boston; "Food Nostrums," by Dr. Charles Harrington, of Boston; "Treatment of Constipation," by Dr. Franz Pfaff, of Boston; "Enteroptosis," by Dr. Mary P. Dole, of Greenfield.

At 2.30 P. M., in Cotillion Hall, meeting of the Section in Surgery. Dr. G. W. Gay, of Boston, Chairman; Dr. J. C. Munro, of Boston, Secretary. General Subject, "Chapters in Ophthalmology and Otolaryngology." Papers will be read as follows:

"On the Occurrence of Retinal Hemorrhage after Middle Age and its Bearing on the Duration of Life," by Dr. Hasket Derby, of Boston; "Anomalies of Muscular Balance," by Dr. O. F. Wadsworth, of Boston; "Some Phases of Lachrymal Trouble and their Treatment," by Dr. David Harrower, of

Worcester; "Contagious Conjunctivitis," by Dr. Myles Standish, of Boston; "Convergent Squint," by Dr. C. H. Williams, of Boston; "Purulent Ophthalmia from the Bacteriological Standpoint," by Dr. W. J. Daly, of Boston; "Brain Complications of Diseases of the Ear," by Dr. J. O. Green, of Boston; "The Fatigue of Deafness," by Dr. C. J. Blake, of Boston; "Nasal Obstruction with Reference to Aural Diseases," by Dr. G. A. Leland, of Boston; "Some of the More Common Affections of the Ear and their Treatment," by Dr. H. L. Morse, of Boston; "Some of the Indications for Opening the Membrana Tympani," by Dr. F. L. Jack, of Boston; "The Ear Complications of Typhoid Fever," by Dr. E. M. Holmes, of Boston.

Reading of the ophthalmological papers will begin promptly at 2.30 P. M.; of the aural papers at 3.30 P. M. Each contributor will be allowed ten minutes, only, in which to read his paper or its abstract. Papers for publication are not necessarily limited.

WEDNESDAY, JUNE 9, 1897.

At 9 A. M., in Cotillion Hall, the Annual Meeting will be held. The following papers will be read:

"The Diagnostic Value of the Examination of the Blood Serum," by Dr. R. C. Cabot, of Boston; "Fistula in Ano: its Palliative and Operative Treatment," by Dr. J. B. Blake, of Boston; "Some of the Uses of the Röntgen Rays in Medicine," by Dr. F. H. Williams, of Boston; "Medical Inspection of Schools," by Dr. S. H. Durgin, of Boston.

Introduction of delegates.

At 12 M., the Annual Discourse, by Dr. Z. B. Adams, of Framingham.

At 1 P. M., at the close of the discourse, the Annual Dinner will be served.

BUREAU OF INFORMATION.

The Bureau of Information which was established two years ago will be continued during the coming meeting. The object of the Bureau is to furnish information of any kind to members and to add in every way possible to their comfort and pleasure while in Boston.

EXHIBIT.

On Tuesday and Wednesday, in Mechanic Building, from 9 A. M. to 5 P. M., there will be an Exhibit, including the usual features.

A valuable collection of original paintings and x-ray photographs, representing pathological specimens and anatomical dissections, will be exhibited.

In addition to the above special exhibit, there will be a display of surgical instruments, books, electrical and orthopedic apparatus, artificial limbs, trusses and carriages.

There will be a demonstration of the x-rays taken by the Röntgen process.

COUNCILLORS' MEETINGS.

The Annual Meeting, at 7 o'clock P. M., Tuesday, June 8, 1897; Stated Meetings on the first Wednesday in October and in February, at the Medical Library, No. 19 Boylston Place, Boston.

FRANCIS W. GOSS, M.D., *Recording Secretary*.
217 Warren Street, Roxbury.

SOCIETY NOTICES.

MAINE MEDICAL ASSOCIATION.—The forty-fifth annual meeting will be held in Common Council Chamber, City Building, Portland, Me., Wednesday, Thursday and Friday, June 2, 3 and 4, 1897.

DR. CHAS. D. SMITH, *Recording Secretary*, Portland.

NATIONAL CONFEDERATION OF STATE MEDICAL EXAMINING AND LICENSING BOARDS.—The seventh annual meeting of this Association will be held at the Hotel Walton, Philadelphia, Monday, May 31, 1897, beginning at 10 o'clock A. M.

Members and ex-members of State Medical Examining Boards, physicians and educators who are interested in the cause of higher medical education are cordially invited to attend.

WILLIAM W. POTTER, M.D., *President*, Buffalo, N. Y.

A. WALTER SEITER, M.D., *Secretary*, Herkimer, N. Y.

RECENT DEATHS.

DR. MAISONNEUVE died recently at Nantes, his native town, in his eighty-eighth year. He was one of the most eminent surgeons of Paris in the days of the Second Empire. He was on the staff of the great hospitals of La Pitié, the Hôtel Dieu and Cochin, and he wrote several standard works on surgical subjects. The urethrotome which bears his name is a valuable instrument, even at the present day, and has not been superseded in the treatment of a certain class of cases.

MR. LOUIS PASCAL CASELLA died at Highgate on April 23d, aged eighty-six years. He will be remembered as the author of many important improvements in scientific apparatus of various kinds, and in particular of the clinical thermometer. Sir William Aitken has perhaps the best claim to be regarded as the pioneer of medical thermometry in England, and Mr. Casella has the credit of being the first maker, if not the inventor, of the clinical thermometer.

Lecture.**THE DIFFERENTIAL DIAGNOSIS OF THE ACUTE EXANTHEMATA, WITH ESPECIAL REFERENCE TO SCARLET FEVER.¹**

BY T. M. ROTCB, M.D., BOSTON.

GENTLEMEN:—Your Professor of Diseases of Children, Dr. W. P. Northrup, has honored me so far as to ask me to open his course on the Exanthemata, and it gives me great pleasure to comply with his wishes.

What I tell you must necessarily, from the time which is given to this lecture, be limited to a few important facts concerning the exanthemata as a group, and to a few salient points concerning the most important of this group, scarlet fever.

In contradistinction to the various diseases of the skin which dermatologists are accustomed to designate as exanthems of local origin are certain acute, specific, infectious diseases which are called the exanthemata. The exanthemata occur most commonly among children, and are practically self-protective, the exceptions being when they develop in an individual more than once.

The exanthemata comprise five diseases, — variola

special, and of the differential diagnosis between the various members of this group you should understand that, though the efflorescence is important, it is not necessarily the essential or exclusive factor of the problem. Thus a papular efflorescence, although significant in most cases of measles, may also be present in other members of the group; while an erythema closely resembling scarlet fever may occur in variola, measles or rubella. You should, therefore, be familiar with the characteristics of all the stages of these diseases, as it is by a careful consideration of the pictures which they present to us as a whole that we avoid being misled by what may or may not occur in any one of the stages, and in fact thus only can be made a correct differential diagnosis in the atypical cases which at times confront us. It is the experience of those in charge of the contagious hospitals that patients supposed to have variola or scarlet fever, from the efflorescence which they present, are sent to the hospital, when no variola, but varicella exists; when no scarlet fever, but measles, or even diphtheria, exists. Again, since antitoxin injections have been used, a class of efflorescences has arisen, the result of such injections, which simulates so closely both scarlet fever and measles that we cannot distinguish them

	VARIOLA.	VARICELLA.	MEASLES.	RUBELLA.	SCARLET FEVER.
Incubation	12 days.	17 days.	10 days.	21 days.	4 days.
Prodromata	3 days.	A few hours.	3 days.	A few hours.	2 days.
Efflorescence	Macules. Papules. Vesicles. Pustules.	Vesicles.	Papules.	Papules.	Erythema.
Desquamation	Large crusts.	Small crusts.	Furfuraceous.		Lamellar.
Complications and sequelæ . .	Larynx. Lungs.		Ear. Lung. Tuberculosis.		Kidney. Ear. Heart.

(small-pox), varicella (chicken-pox), measles (rubeola), rubella (German measles, rōtheln), and scarlet fever.

This group of diseases is characterized by certain conditions common to all. They run a definite course and are self-limited. Each member of the group is supposed to have its own special micro-organism which produces it, but none of these organisms have as yet been discovered. The course of all of these diseases from the time when infection takes place up to the appearance of their later manifestations may be divided into four distinct stages:

(1) The stage of incubation, during which the micro-organism has entered the individual and, so far as external manifestations are concerned, is lying dormant.

(2) The prodromal stage, when certain general symptoms appear, varying according to the characteristics of the special member of the group represented.

(3) The stage of efflorescence, during which an efflorescence appears on the skin.

(4) The stage of desquamation.

You will see by this table how the different stages vary according to the member of the group in which they occur. One of the first points to which I wish to call your attention is that in the recognition of a

from these diseases, and when, too, these cases are added to efflorescences arising from a number of drugs, such as belladonna, we are forced to admit that it is not safe in making a differential diagnosis between the acute exanthemata to depend on the character of the efflorescence.

Keeping this table before you, I will briefly refer to its contents.

The length of the stage of incubation in variola is about twelve days, in varicella about seventeen days, in measles about ten days, in rubella about twenty-one days, and in scarlet fever about four days.

The characteristic prodromata of typical cases of variola is three days in length, and in young infants is commonly represented by convulsions, restlessness, quick pulse and high temperature (104°, 105° or 106° F.). In varicella it is a few hours in length, and only shows slight malaise. In measles it is three days in length, with heightened temperature (101°, 102° or 103° F.), cough, coryza and lachrymation. In rubella it is only a few hours in length, with slightly heightened temperature and malaise; and in scarlet fever it is one or two days in length, and accompanied by apathy, nausea, vomiting, sore throat and high temperature (103°, 104° or 105° F.). Observe how different are these groups of symptoms in their prodromal stages, and how valuable they are for differential diagnosis.

¹ The Opening Lecture in the Course on Children, delivered by invitation of the faculty at the Bellevue Hospital Medical College, New York, December 16, 1896.

There is also a peculiar range of temperature characteristic of each disease. In variola, a rapid rise of temperature on the first day to 104° or 105° , and remaining at about this height to about the third day, with slight remissions in the morning, and a decided fall in temperature almost to the normal on the fourth day (this period being called the fever of invasion), then a slightly raised temperature on the fifth and sixth days, and a rise to 104° or 105° again on the seventh, eighth and ninth days (the fever of suppuration), and then falling by lysis to the normal at about the thirteenth or fourteenth day.

In varicella, a slight rise of temperature with the appearance of each successive group of vesicles, the temperature falling to the normal in a few days.

In measles, a sudden rise on the first day, then falling almost to the normal on the second day, and again rising on the third day as the efflorescence appears, remaining up for two or three days, and then on the fifth or sixth day dropping by crisis, or a broken crisis, and becoming normal on the seventh, eighth or ninth day.

In rubella, a slightly raised temperature lasting for a few days.

In scarlet fever, rising steadily for four or five days, and falling by lysis to the normal at about the tenth or eleventh day.

We now arrive at the stage of efflorescence, which in variola consists of macules, papules, vesicles and pustules, all developing one from the other in slow progression. In varicella, vesicles develop from macules and papules so rapidly that we speak of the lesion as essentially vesicular. In measles, papules. In rubella, papules; and in scarlet fever a punctate erythema.

Let us now for a moment observe the topography of the different members of the group. What is the geographical distribution on the skin characteristic of each of these diseases? Supposing that we make certain arbitrary divisions, the head, the neck, and the thorax, and observe in which of these areas the efflorescence is most apt to begin in the several diseases. This is a very important point, and is often of great aid in making the differential diagnosis of a doubtful case. Thus in variola the efflorescence is most apt to begin on the forehead; in varicella on the face, behind the ears, and on the back; in measles on the face; in rubella on the face and thorax, being rather irregular in its distribution; while in scarlet fever it first appears on the neck and thorax.

As illustrating the locality and appearance of these efflorescences, I will now show you first a case of varicella.

This little girl, after feeling sick for a few hours, presented this vesicular efflorescence on her face and back, which then quickly covered the whole body. You will notice that the face is not swollen.

This second case, a little girl six years old, you will notice has a papular efflorescence on her face, which is much swollen. It is a case of measles. The papules, as you see, have coalesced on the face, and the whole face has a blotchy appearance. This in connection with a few papules on the chest, some of them arranged in rather a concentric shape, and somewhat lighter in color than those on the face, complete the typical picture of the disease, measles, which you see in comparison with the next case which I shall show you, has an ugly and almost repulsive appearance.

This next case, on the contrary, which is one of scarlet fever, is an essentially becoming disease. The eyes are bright and clear, where those of measles were dull and reddened. The skin of the forehead and nose, and about the mouth is white and smooth in comparison with the rough, congested skin in the case of measles. This boy, as you see, presents the efflorescence of scarlet fever, a punctate erythema, markedly located on the neck and thorax, so that the mere location of the efflorescence would make us state at once that one was a case of measles and the other of scarlet fever.

As to the remaining points of differential diagnosis in the exanthemata, I have only time to state that the stage of desquamation shows in variola large crusts, in varicella small crusts, in measles a fine furfuraceous mealy condition of the skin. Rubella, as a rule, shows no desquamation; and in scarlet fever there is a lamellar desquamation often amounting to large strips of skin.

The complications and sequelæ of the different members of the group differ according to the disease. Those which are particularly to be thought of and apprehended are, in variola, an invasion of the larynx and the lungs; in varicella, nothing especial; in measles, the eye, the lung, and a tendency to general tuberculosis; in rubella nothing especial; and in scarlet fever the kidney, ear, and heart.

I shall now, gentlemen, occupy the remainder of the time allotted to me in speaking of certain important conditions connected with the disease scarlet fever. Scarlet fever is one of the group of exanthemata, and is characterized by a short incubation, a short prodromal stage, erythematous efflorescence, a pronounced desquamation, and a long course. The micro-organism which produces it has not yet been discovered. The streptococci which are so often found in this disease seem to be merely manifestations of a secondary infection, as they do in diphtheria. So far as infants and young children are concerned, scarlet fever is the most important of all the exanthemata. Not being controlled by vaccination, as is variola, it occurs far more frequently than does that disease. Its complications are so much more serious, and its sequelæ so much more common and grave than measles or varicella that a thorough knowledge of all its manifestations is exceedingly important to the physician whose practice is among children.

Scarlet fever is the most irregular of all the exanthemata in its virulence and in the manifestations which it presents in different individuals. The skin appears to be the chief vehicle of the contagium, which has a wonderful tenacity for clothing and other articles, and may be capable of reproducing the disease for many months. In contradistinction to measles, which is known to be highly infectious in the early stage, scarlet fever appears to be most infectious in the later stages, and the contagium to be most likely to be disseminated during the stage of desquamation. As illustrative of this fact, I will report to you the cases of two children who were under my care a few years ago.

A boy six years old and a girl four years old slept in the same room, with their beds touching each other. The boy was taken sick May 1st, but remained in the same room with his sister during that day and the following night. He was seen by me early on the morning of May 3d, and was then found to have scar-

let fever. His sister was taken to the country and the boy was left in charge of a trained nurse. There was absolutely no communication between the town-house and the country-house, either by people, clothes or letter. I myself did not again see the boy during his sickness, having placed him under the charge of another physician.

On June 1st, I was called to see the girl, and found that she had scarlet fever. There were no other cases of scarlet fever in the vicinity of the country-house where she had remained since leaving the city.

The boy at this time was desquamating freely, and four days previous to the girl's being taken sick a letter written by him had been sent to her, and she, after having had it read to her, had been allowed to keep it under her pillow.

A careful study of this case led to but one conclusion, that the boy during the period of his desquamation had infected his sister at a distance of twenty miles by enclosing the contagium of scarlet fever in an envelope. The girl, although she had been in the same room with the boy for thirty-six hours at the beginning of the disease, and although susceptible to the disease, had not contracted it at that time, owing to its very slightly infectious nature in its early stages. On the other hand, the incubative stage of scarlet fever being only a few days, and many instances having proved that the disease is very infectious during its period of desquamation, it was evident that the girl had been infected by means of the letter.

In the following year, on May 20th, I was again called to see the same boy. He had been well in the morning, but in the afternoon was found to have a high pulse and temperature, with coryza and lachrymation, so that it was deemed best to send the sister, who had been in the nursery only a few hours with her brother after he had been taken sick, to another house, while the boy was absolutely isolated. Three days later the boy was found to have measles. Ten days later the girl was attacked by measles. This case merely emphasizes the now commonly accepted belief that measles, in contradistinction to scarlet fever, is highly infectious in the early hours of the disease.

Scarlet fever may occur at all ages but the vulnerability to the disease is decidedly lessened after the tenth year. There is no drug which will prevent scarlet fever or cure it. It is a self-limited disease, and is apparently benign or malignant according to the vulnerability of the individual. Thus we may meet with many cases where the symptoms are so mild and the convalescence so rapid that the disease runs as uneventful a course as does the usual case of measles. Again, in the same family at the same time another child may be attacked with severe prodromal symptoms, convulsions, delirium, and later uremia, endocarditis, or purulent otitis media. These cases are not necessarily fatal but, rendered dangerous from the gravity of their sequelæ, may still be considered benign in comparison with a third class of cases, which also may arise in the same family with the benign cases, but which is so terrible in its manifestations and so universally fatal that it can well be called malignant.

Bearing in mind what I have just told you, you will, I know, agree with me that we should discountenance the opinion so often expressed by the laity, and too often supported by the physician, that it is well for children to have scarlet fever while they are young

and get through with it, on the ground that they may contract it at a later period of life when the type of the disease may be more severe. The assertion that the type of the disease is more severe in adults than in children is not corroborated by my experience. In either case it is probably the individual vulnerability which makes the disease benign or malignant, and we have no right to encourage the parents by our advice to take the risk and responsibility of testing whether the individual child happens to have or not a special vulnerability to the scarlet fever organism, and whether it will contract the infection and the benign or malignant form of the disease result. On the other hand, the sequelæ are far more dangerous and far-reaching in the child than in the adult. For instance, a large proportion of our deaf mutes have had their deaf-mutism originate in an otitis secondary to scarlet fever. The commonly occurring and often intractable form of otitis which accompanies scarlet fever may not only render the child deaf, but in a case where the child has not learned to talk, may lead to deaf-mutism.

There are, then, three distinct types of scarlet fever apparently caused by the same micro-organism, but determined by the vulnerability of the individual. The first benign and harmless; the second benign, but dangerous from its complications and sequelæ; and the third malignant. The first and third types can, after what I have told you, be described in a very few words.

In the first class, for instance, a child four years old, exposed to scarlet fever four days previously is on the fourth day attacked with vomiting, a reddened throat, a temperature of 104° F., and thirty-six hours later a punctate erythema appearing first on the neck and thorax and later extending to the arms, face and legs. No other symptoms arise during the course of the disease and the temperature falls slowly to the normal, as I have shown you when describing the comparative temperatures of this group of diseases. Desquamation of a lamellar character occurs in the second or third week. In these cases the urine is usually lessened during the height of the fever, gradually returns to the normal as the temperature falls, and during the stage of desquamation increases to such an extent as to almost represent a polyuria, this being a conservative effort of nature to restore the function of the kidney to the normal. In these cases the throat though reddened often does not cause sufficient discomfort to demand especial attention.

The differential diagnosis from measles in the prodromal stage by the appearance of the throat is as follows: In scarlet fever there is a general intense redness of the whole throat, including the hard palate. The entire mucous membrane is affected, and the small dots, which in connection with the hyperemic condition of the skin represents the condition of a punctate erythema from being localized on the moistened mucous membrane, have a little darker appearance than the adjacent reddened tissue. In measles, on the contrary, the mucous membrane of the throat has a blotchy appearance and is of a darker red than is seen in scarlet fever, while the mucous membrane between these blotches is but slightly congested in comparison with that of scarlet fever.

In these benign cases the diet should be entirely of milk, because in all cases of scarlet fever, even of the mildest character, there is in all probability a tendency

to nephritis, and if a nephritis develops, a diet of milk is the best treatment for the disease.

This first type of scarlet fever, therefore, is essentially benign, requires no drug treatment, and will do well with careful nursing, unless a nephritis is precipitated by injudicious diet or nursing.

The third or malignant type of cases can be described in still fewer words. We know of no treatment which is of the slightest avail in these cases. They all die. The streptococcus toxin in the future may be of some avail where the violence of the symptoms depends upon the secondary infection, but in all probability it is the primary micro-organism of scarlet fever which in this class of cases kills the child. Until this primary micro-organism has been discovered and its toxin produced, we shall probably never be able to cure the disease. It may perhaps impress this class of cases on your minds for me to describe a case which I saw some years ago in consultation.

A girl, eleven years old, was perfectly well and strong, and had no other diseases up to January 10th. In the middle of the day she felt very ill and vomited. Her pulse was 150, and her temperature was 104.5° F. The pharynx and tonsils were much reddened, but there was no exudation or membrane to be seen. An efflorescence of a scarlatinal type appeared on the chest in the afternoon. The vomiting continued through the night and up to the morning of January 11th. The child was conscious, but dull. The pulse was 150, and the temperature was 105° F. At 4 p. m. the face became puffy, and the efflorescence was well marked on the body and extended to the extremities. The child was wandering and stupid and the temperature rose to 108° F. The extremities became livid and the vomiting began again. At 6.30 p. m. the temperature, after the internal administration of various remedies, was found to be 107° F., and at 10 p. m. 106° F., and the pulse 160, weak, and difficult to count. At 6 a. m. on the 12th, forty-eight hours from the appearance of the first symptoms, the child died.

The case was a perfectly hopeless one from the beginning, as every method of treatment which could be thought of was tried and proved absolutely fruitless. Tub-bathing with water at different temperatures, and finally sponging with ice-water, had no effect whatever on the temperature or the general symptoms.

The second type of what I have called the benign cases of scarlet fever is of much interest and is well worthy of study. While there is no treatment by drugs for the first and third types, which I have just spoken of, and no known treatment of any kind which will cure the third, there is no class of diseases in children which needs more general treatment, including drugs, and gives more satisfactory results than this second class of cases. Children have such wonderful recuperative powers that even the seemingly desperate cases may recover, and organs apparently crippled be restored to a fair working capacity. As in every disease, a knowledge of the pathology is of primary importance if we expect to intelligently make the diagnosis and carry out the treatment, so in this more serious class of cases of the benign form of scarlet fever we should appreciate what organs are affected, and what morbid conditions are most likely to be met with.

The organs primarily affected in scarlet fever are the skin and the throat.

The principal complications which arise in the

course of the disease are connected with the ear and the cervical glands.

The chief sequela, and the only one which is at all common, is nephritis. Cardiac disease, commonly secondary to the nephritis, may occur. Lesions of the other organs are unusual, and have no direct connection with the scarlet fever. They are due partly to the fever and partly to the septic processes which have arisen in the course of the disease, and are represented, as would naturally be expected, by a congested condition of the various internal organs, and by the usual changes which are found in pleuritis, pericarditis, endocarditis and meningitis.

The Skin. — Macroscopically the morbid conditions of the skin in scarlet fever, though varying in their manifestations, are usually represented by an intense general erythema, covered thickly with minute macules which are of a darker red than the accompanying hyperemia. Minute white spots may also appear thickly scattered over the reddened surface, probably arising from areas of unaffected skin existing in the midst of the general hyperemia. No evidence of this hyperemic condition, which is so pronounced during life, is found after death.

According to Neumann, microscopic examinations of the skin explain in a measure why scarlet fever is so much more likely to be infectious during the stage of desquamation than is measles. In contradistinction to the pathological processes which are found in the skin in measles, and which affect chiefly the blood-vessels and glands, a very different picture is presented on examination of sections of skin taken from scarlet fever. In the latter we find the pathological process represented especially by exudative cells, which are very numerous and are closely packed together, reaching even up to the horny layer of the epidermis. Occasionally these exudative cells may finally take the place of the epidermal cells, appearing on the free surface of the skin, and are gathered thickly among the excretory ducts of the cutaneous follicles. You will thus readily understand why the tissue proper of the skin and its epidermis presents no marked changes in measles, and why the epidermal cells are far less likely to carry the contagium than in scarlet fever where the possibility of contagion exists until the desquamation has entirely ceased.

The Throat. — The earliest lesions of scarlet fever appear on the mucous membrane of the hard and the soft palate. This appearance is very similar to the efflorescence which is seen on the skin, except that the minute white spots do not appear on the congested mucous membrane. The pathological conditions which occur in the throat in scarlet fever may be either simply catarrhal or the result of one of the more severe inflammatory conditions affecting the tonsils, the pharynx and the larynx.

One of the most marked features of scarlet fever is the predisposition which it entails to the incursion of pathogenic germs other than those which we believe to cause this disease. Thus, in addition to the inflammatory lesions produced by the scarlet fever organism, an acute exudative inflammation of the mucous membrane apparently caused by the streptococcus pyogenes may be associated with them. We may conclude indeed that in scarlet fever the mucous membrane of the throat is rendered peculiarly vulnerable to the invasion of pathogenic germs, and that where the morbid condition in the throat is represented by a pseudo-mem-

brane it will be found in the great majority of cases that the process is due to streptococci. On the other hand, where diphtheria is prevalent and the opportunities are favorable for exposure, a large portion of the cases may be due to the Klebs-Löffler bacillus.

In addition to the lesions of the throat just described, the micro-organism of scarlet fever may attack the naso-pharynx. In this way also by direct extension through the Eustachian tubes secondary aural lesions may be produced. The morbid changes in the naso-pharynx which thus take place may result in a thickening of the tissues which in some cases lasts for many months after the fever has run its course.

The Ear.—The pathological condition of the ear which is most commonly met with in scarlet fever is an acute inflammation of the middle ear. This inflammation is likely to result in the destruction of tissue, the formation of adhesions, the establishment of a long-continued suppurative process, and an accompanying necrosis.

Cervical Glands.—There may be hyperplasia of the cervical lymph-nodes. This condition is sometimes accompanied by inflammatory edema of the tissues of the neck, which may go on to suppuration and even to gangrene. In these cases streptococci are found in the glands and in the areas of suppuration. The infection is supposed to originate in the throat. The enlarged glands are, as a rule, indicative of secondary or mixed infection though it is possible that the slighter forms of enlargement may be due to reflex irritation with resulting hyperplasia from the scarlet fever contagium. In the severe form the glands are at times very much enlarged, and where a gangrenous process results the blood-vessels may be affected to such an extent as to be ruptured.

The Kidney.—In scarlet fever, as in a number of other infectious diseases, there are certain poisons produced in the course of the disease which are probably soluble in character. The result of bacteriological cultures in scarlet fever have shown that in a number of cases there is a general streptococcus infection, the infection probably coming from the lesions in the pharynx. In these cases of general infection streptococci may be cultivated from most of the organs of the body, there being a general septicemia. In a number of these cases extensive lesions may be found in the kidneys and yet these lesions may bear no relation whatever to the presence or absence of streptococci. In like manner streptococci may be found in the kidney without any lesion of the kidney. These lesions are diffuse and affect both kidneys and all parts of the kidneys. From the best evidence which we have it would seem that the virus, or whatever it is which produces the lesions in the kidney, is not a living organism but is a soluble chemical poison produced by the organisms of scarlet fever, or by some other organism located in some other part of the body. This soluble poison when produced elsewhere is taken locally into the blood and affects various parts of the economy. In post-mortem examinations of scarlet fever certain lesions will be found in the kidney.

These lesions, according to Councilman, may be divided into two classes: (1) represented by simple degeneration of the epithelium, and (2) represented by marked changes in the tissues of the kidney.

In the first class of cases the soluble poison may only affect the integrity of the capsular epithelial cells of the glomeruli. The poison may produce cer-

tain degenerative changes in these, but need not be accompanied by any proliferation of cells or by any condition which may be characterized as inflammatory. It is more than probable that these simple degenerative lesions are accompanied during life by evidence of albuminuria, and in case death takes place there may be no macroscopic evidence of any lesion in the kidneys. Careful microscopic examination, however, will show a condition of degeneration in the capsular epithelium of the glomeruli. Associated with this there will usually be found cloudy swelling of various degrees of intensity in the cells of the convoluted and the smaller collecting tubules. The degeneration here is rarely of a fatty character. Clinically, in the purely degenerative changes there may be only albuminuria with the presence of faint hyaline casts and here and there a few leucocytes.

In the second class, owing to a greater intensity in the action of the poison, or to some possible difference in its character, more marked changes may take place in the kidney and may be accompanied by the degenerative lesions which are distinctive of the first class. Different forms of lesions may occur in the second class, and, according to the predominance of one form over the other, may characterize a special form of renal disease. Thus these lesions may be divided according to their anatomical distribution into interstitial, where there is a marked proliferation of the interstitial tissue, and glomerular, where the lesions are chiefly confined to the glomerulus and its capsule.

In the interstitial form there may be found in the interstitial tissue between the tubules accumulations of cells which are probably due to a proliferation of cells of the capsule and of the connective tissue. These cells are most of them epithelioid in character and show very few leucocytes mingled with them. This form of nephritis should be considered as purely interstitial, since its lesions are in no way related to those of the epithelial tissue. There is both a general and a focal infiltration of cells in the interstitial tissue. The focal infiltration is found principally in the cortex of the kidney and about the glomeruli, the glomerulus frequently appearing as a centre from which the infiltration extends into the interstitial tissue between it and the surrounding tubules.

Clinically, in this form there may be little evidence of the severity of the lesions. There may be, however, albuminuria corresponding to what is seen in the purely degenerative class. The quantity of the urine may be very little diminished, and casts may be present, as well as a certain number of desquamative epithelial cells and leucocytes.

These lesions are not confined to scarlet fever, but may be found in diphtheria, in measles, and in other infectious diseases of children. They are not common in the infectious diseases of adults.

The other form of nephritis, called the glomerular, is much more frequently found in scarlet fever than is the interstitial form and may be considered almost typical of the disease. In this glomerular form the chief lesion of the disease consists essentially in a proliferation of the capsular epithelium combined with hyperplasia of the connective tissue.

The proliferation of the capsular epithelium leads to the formation of masses of cells within the capsule between the glomerular capillaries and the capsule. These cells evidently result from the proliferation of

the capsular epithelium. As a result of this there may be greatly increased pressure on the vessels of the glomerulus with possibly obliteration of these vessels. The cellular infiltration of the interstitial tissue is not so extensive as in the other form. Accompanying these changes in the glomerulus there is almost always more or less hemorrhage both in the tubules and in the interstitial tissue.

It is this capsular glomerulo-nephritis which gives the most marked clinical evidences of the extent of the lesions in the kidney. In this form dropsy is almost always present, the amount of urine is greatly diminished, and in more severe cases there may be anuria. Blood-casts are found more frequently in the urine than in the interstitial form. The diminution in the amount of the urine points to the involvement of the glomerulus. Even severe cases of this form may be recovered from. In a certain number of cases from this form of nephritis a chronic nephritis is developed. These two forms of nephritis should be separated from each other, although transitions between their lesions are found. Usually they can be distinguished macroscopically.

We can, therefore, recognize three pathological conditions of the kidney in scarlet fever: first, the purely degenerative; second, the acute interstitial; and third, the capsular glomerular.

The Heart.—The pathological conditions of the heart which are at times found in scarlet fever do not differ in their macroscopic appearances from those met with in other diseases. Cardiac disease occurring in the course of scarlet fever may arise in two ways: (1) from the general septic condition existing during the period of the height of the temperature and general efflorescence, and represented usually by an endocarditis; (2) at a much later period from a nephritis which has arisen as a complication, and following which, from the resulting increased blood pressure, enlargement of the heart has been produced, which may be represented by hypertrophy, or by dilatation, or by both.

During the stage of efflorescence, especially if the temperature is considerably heightened, there may appear in the urine a small amount of albumin, but this disappears as the temperature subsides. It is probably only the result of the fever, as in many other diseases accompanied by a high temperature, and is not to be confounded with the albuminuria of the nephritis which in some cases complicates the stage of desquamation.

There is considerable reason to suppose that a mild form of nephritis accompanies almost every case of scarlet fever, although in many cases no clinical symptoms pointing towards the kidney appear and nothing abnormal is found on examination of the urine. This latter statement, however, rests to such a degree on the authority of the general practitioner, rather than on that of the expert in urinary analysis, that we shall probably in the future find the number of cases which show nothing abnormal in the urine greatly lessened when the number of expert examinations of the urine in mild cases of scarlet fever has increased.

In this second form of scarlet fever the gravity of the disease arises from the various complications and sequelæ, which may be of varying degrees of severity.

When the temperature remains heightened at the end of the period of efflorescence and continues into

the period of desquamation, especially if there is local pain anywhere, we should suspect that a nephritis may be developing. When the temperature after having become normal rises again we should expect such complications as otitis, and suppuration of the subcutaneous tissues of the neck or that the heart is involved. Certain cases are at times met with in which the high temperature, or the especial vulnerability of the child to the scarlet fever contagium, causes the symptoms to vary considerably from the typical form and be unusually grave.

As an instance of this class of cases I will report to you that of a boy six years old, seen in consultation with Dr. Loring. The invasion of the disease was characterized by restlessness and sore throat which were soon followed by vomiting and delirium. The temperature on the first day rose to 106° F. During the first three days the pulse could not be counted. The heightened temperature continued until the sixth day from the beginning of the prodromal symptoms. There was great gastro-enteric disturbance, and during the first forty-eight hours there was almost continuous vomiting. This was succeeded on the third day by frequent profuse, and often involuntary discharges from the bowels. These discharges continued until the fifth day. On the fourth day a slight erythematous efflorescence appeared on the neck and chest, and on the fifth day it extended all over the body and was of an intense character. On the sixth day pain in the wrists began but it disappeared in twenty-four hours under the administration of salicylic acid. At this time, also, there was considerable swelling on the left side of the neck which gradually disappeared in four or five days. When the fever was at its height there was considerable cyanosis, with quickened respiration. The pulse at this time was weak and difficult to count. Whenever the temperature reached 105° F. the child was placed on a pillow in the bath and kept there until the temperature was reduced three or four degrees. The time required to accomplish this was usually from one to one and a half hours. While the child was in the bath stimulants and milk were given to it. The temperature of the water was at first that of the child, and was gradually reduced to about 90° F. During the first four days the child was either delirious or in a comatose condition, and when in the bath would pass its urine and fecal discharges involuntarily. The high temperature continued until the sixth day when it fell and the baths were omitted: the temperature continued to fall by lysis until it reached the normal degree on the sixteenth day from the invasion of the disease. After this the child had no unusual symptoms and made a rapid recovery. There were no complications. The desquamation took the usual course.

Scarlet fever may begin with such great cerebral excitement as to lead us to suspect meningitis and it may not be possible to determine the diagnosis until the efflorescence has appeared, which may not be until even the eighth or ninth day.

Most of the complications which arise in scarlet fever are due probably to the action of streptococci, either isolated or associated with other micro-organisms. These micro-organisms produce serious symptoms, which are often followed by death, either directly by giving rise to septicemic processes or indirectly by nephritis.

It is supposed that the infection which complicates

scarlet fever enters the system commonly through the pharynx either by direct absorption or by inhalation of these organisms.

It is of great importance to detect by means of frequent analyses of the urine the beginning of either the milder forms of renal disturbance or the more severe forms of nephritis, usually represented by that which is called capsular glomerulo-nephritis. If carefully watched for, the appearance of albumin will almost always precede the clinical symptoms. It is quite frequently the case that a suspicion is first aroused as to the presence of nephritis, either by vomiting or edema of the face, especially about the eyes, commonly occurring during the period of desquamation, from the eighteenth to the twenty-fourth day. Under these circumstances the urine will be found to be diminished in quantity and to contain albumin. The daily amount of the urine may be reduced as low as three and one-half ounces or even lower. The microscopic examination of the urine does not materially differ from that which results from the other forms of nephritis in their early stages, but later you may find that fatty casts are less numerous in the nephritis of scarlet fever because there is less fatty degeneration in the renal epithelium. The earlier in the course of the disease the symptoms of nephritis appear, the more severe, as a rule, will be its type. The extent of the albuminuria is of less consequence than the total quantity of the urine. A rapid and extensive diminution of the urine is ominous, as it indicates the accumulation of nitrogenous waste in the blood and the danger of a resulting uremia. The albumin occurring early in the disease is more apt to be in large quantities than when it appears first in the third or fourth week. Hematuria is frequently present in this form of nephritis but ordinarily of itself adds little to the gravity of the disease. The edema of the face may be followed by a rapid involvement of the ankles and legs, and at times may become general. During the course of a general edema the desquamation is apt to cease, returning on its disappearance. The edema may last for months or may pass away quickly; it may be entirely absent, but in such cases the nephritis is almost invariably of a light grade.

At times during the presence of a general edema serous effusions into the pleura may occur. Edema of the lungs and brain, though very rare, may also take place. Instead of a slow development beginning with edema of the face, we may have an acute attack, ushered in by fever, vomiting, headache, edema, amblyopia, coma and convulsions.

Relapses may occur many weeks after an attack of scarlatinal nephritis, and we should watch the case with the greatest care for several months. The nephritis of scarlet fever, although it may last for months, has a tendency in children ultimately to recover, on account of their wonderful recuperative powers. It is also rare for the renal disease following scarlet fever to become chronic.

Retinitis and amaurosis at times occur during the progress of the nephritis in scarlet fever. In these cases of amaurosis it has been noticed that, although the loss of sight may be complete, almost always where uremia and amaurosis are coincident, there is found no perceptible change in the retina, no congestion of the papillae, no increase of intracranial pressure, and no intense edema of the brain. The sight under these circumstances may be recovered completely.

We find in quite a number of cases of capsular glomerulo-nephritis a rapid hypertrophy of the left ventricle. This cardiac complication is not to be confounded with the endocarditis which I have already spoken of as secondary to the scarlet fever, and which is supposed to be caused by its special poison or by the streptococci which I have already described as being present in the disease. It is, in fact, not the direct result of the scarlet fever, but is secondary to the nephritis, and is, in this sense, tertiary to the scarlet fever. We, therefore, do not find this acute cardiac hypertrophy in the earlier stages of scarlet fever; but when a capsular glomerulo-nephritis is once established, it may take place in so short a period as a week. This rapid hypertrophy has usually been observed in children between the ages of three and six years. At this age a physiological hypertrophy of the heart exists, possibly caused by a continuance of the aortic narrowing in the neighborhood of the ductus arteriosus, and the heart will thus be more readily affected by increased blood pressure. Besides the cardiac hypertrophy, we may at times have an acute dilatation of the heart in these cases. This is a serious condition, which must be guarded against, and when it occurs must be recognized at once. These various complications very frequently recover completely, as it is seldom that any extensive changes in the muscles of the heart take place.

We should be careful about using diuretics which might irritate the kidney. Acetate of potash is one of the safer diuretics in this complication. In severe cases, with general edema and threatening uremia, cathartics are rather more certain in their action than diaphoretics and diuretics, and are especially indicated where, as is usually the case, constipation is present. Podophyllin in doses of one-tenth of a grain may be given to a child five years old, and be repeated a number of times. It usually acts quickly. The compound jalap powder, in doses of five to ten grains, may also be given where a rapid and decided derivation by the intestine is indicated.

Having provided for the proper movement of the bowels, if the skin is hot and dry and uremic symptoms (usually represented by anuria, somnolence, amblyopia and headache) are present, the hot pack, either wet or dry, should be resorted to. I prefer in these cases to have the child wrapped in a blanket and placed directly in a tub containing water at a temperature of 105° to 110° F. The child should be kept in the water fifteen or twenty minutes, or even longer if necessary, and should then be taken from the wet blanket, enveloped in hot, dry blankets, and kept in them until the skin has become moist and reaction has taken place. While the child is in the bath milk can be given to it, and stimulants if they are indicated by a weak or an intermittent pulse.

In addition to this treatment, muriate of pilocarpine in doses of one-twentieth of a grain should be given by the mouth to a child of two years, and subcutaneously if desired to a child five years of age. In these cases of threatened uremia convulsions sometimes appear quite suddenly. Under these circumstances enemata of hydrate of chloral, five to ten grains dissolved in water, are of value in controlling the nervous phenomena. I prefer, however, to use a combination of bromide of potash and hydrate of chloral.

Where the ascites is extreme, paracentesis abdominis is often of great value, not only in relieving the press-

ure, but also in increasing the action of the diuretic which perhaps before was not acting freely. Digitalis is a valuable remedy especially adapted to the treatment of the nephritis of scarlet fever and to that of the cardiac changes which result from it. By the administration of this drug the flow of urine is increased. It is best given in the form of a freshly prepared infusion, in teaspoonful doses every four hours, to a child five years old. Diuretin, five grains dissolved in water and given two or three times in the twenty-four hours, has proved of considerable value in my cases, and is apparently harmless.

I speak of special ages, such as five years or two years, merely as a guide by which you can judge what the proper doses should be at the other ages.

I have not time to dwell upon the various other complications of scarlet fever, such as the acute inflammation of the joints and synovitis. I must, however, before ending this lecture impress upon you the importance of prophylaxis in the treatment of cases of scarlet fever where as complete an isolation as possible should always be enforced and where the diet should be as nearly one of milk as the case will permit. The remaining details of the treatment of scarlet fever I shall leave for Professor Northrup to give you in his coming lectures on this subject.

As illustrative of the benign type of scarlet fever, with complications, I will report to you the case of this boy, seven years old, who is said to have been well until eighteen months ago, when he had an attack of scarlet fever, mild in form and not accompanied by severe symptoms. In the latter part of the attack his temperature rose, and he began to have dyspnea and dropsy. Since that time he has been slowly but steadily growing worse. As you see, he has extensive edema of the face, chest, arms, abdomen and legs. He is somewhat cyanotic, and his breathing is so much affected that he is unable to lie down, the orthopnea compelling him to be supported in a semi-recumbent position. On closer examination you see there is slight pulliness about both eyes, that there is a yellow tinge to the conjunctivæ, and that the lips and tongue are cyanotic. The extremities are cold to the touch and their skin pits readily on pressure. The skin of the whole face is dry and harsh and in some portions is covered with fine scales. In addition to the edematous condition of the walls of the abdomen, a distinct fluctuation is found on palpation, showing that there is fluid in the abdominal cavity. An examination of the lungs shows that there is dulness over both bases behind; and over these areas, as well as over the whole front of the chest, fine moist râles can be heard, indicating an edematous condition of the lungs. On examining the heart I find that its impulse is most distinct in the sixth interspace a little outside of the mammary line. The area of cardiac dulness extends from the second rib on the left to one inch to the right of the sternum, in an area corresponding to the third interspace and fourth rib. The dulness then extends to the left, across the sternum, to a point one inch outside of the mammary line and as low as the sixth interspace, corresponding to the cardiac impulse. A loud systolic murmur can be heard over the region of the cardiac impulse, and is transmitted so that it can be heard in every part of the thorax. The total amount of urine in twenty-four hours has varied from 30 to 35 ounces. An analysis of the urine gives the following results:

Color	darker than normal.
Specific gravity	1.013.
Reaction	acid.
Urophein	diminished.
Indican	increased.
Chlorides	diminished.
Albumin	four-tenths per cent.
Sugar	absent.
Sediment: very slight and flocculent.	

Microscopic examination shows numerous short hyaline casts, and granular casts; an excess of renal epithelium; considerable abnormal blood; an occasional white corpuscle; one or two blood-casts; many hyaline and granular casts with one or more renal cells adherent; occasional fatty renal cells and casts with a few fat drops adherent.

You see that he is unable to lie down with comfort on account of the dysnea arising from the accumulation of fluid in the stomach. The cyanosis is so marked and the child is in so much distress that it is evident immediate relief should be given, not only to the general symptoms, but also to the great tax which is being imposed upon the already disabled heart. Unless some relief to these symptoms is given, it is very likely that he will die suddenly from heart-failure. I shall, therefore, withdraw a certain amount of fluid from the abdominal cavity, which will, I think, be followed by considerable relief to the dyspnea.

This case illustrates some of the points in the pathology and clinical symptoms of scarlet fever to which I have already referred. Of course in so late a stage of the disease as this it would be impossible to make a definite diagnosis as to the condition of the kidney and heart. It is possible that during the stage of efflorescence an endocarditis such as might complicate the earlier symptoms of scarlet fever may have been present, and may have been followed by a pathological lesion of the valves. The history of the case, however, shows that the course of the scarlet fever was a mild one, and that whatever complications followed arose at a later stage of the disease during desquamation. It would seem probable, therefore, that the symptoms of edema and cyanosis which appeared in this later stage of the disease were caused by a disturbance of the kidney. As I have already told you a renal complication is most common in the later stages of scarlet fever. The physical examination shows that there is a complication of the heart represented by cardiac dulness and a mitral systolic murmur. The examination of the urine shows us that it is probable that there are organic changes in the kidney as well as in the heart, although we cannot say definitely that such conditions as we find in the urine have not been produced by a cardiac lesion followed by passive congestion of the kidney. Therefore, although we cannot decide without a post-mortem examination whether both kidney and heart are affected, we can at least suppose that the following sequence of complications has resulted and has produced the present clinical symptoms.

The child had scarlet fever in a mild and apparently uncomplicated form until it reached the stage of desquamation. During the latter part of this stage a lesion of the kidney, presumably of the capsular glomerular form, occurred, and owing to the increased blood-pressure which finally resulted from the changes in the kidney, hypertrophy of the heart, presumably followed by dilatation, appeared. If I have correctly read this sequence of lesions, we have, then, cardiac enlargement secondary to renal disease and tertiary to the original scarlet fever contagium.

The prognosis in this case is very unfavorable. Although we know that in children dilatation of the heart may be entirely recovered from, yet as long as this condition exists there is danger of sudden death from cardiac failure. Where the cardiac dilatation results from extensive disease of the kidney, especially in the form which we most commonly meet with in scarlet fever, capsular glomerulo-nephritis, the chances are that this failure will take place before the nephritis has been recovered from, when a patient has been reduced to such a degree as is the case with this boy.

The treatment should be absolute rest so as not to tax the muscles of the heart more than can possibly be avoided. To relieve the intra-abdominal pressure, which augments the edema of the lungs and interferes with the action of the heart, paracentesis of the abdomen should be performed, as I have just told you. Hot baths should be given to increase the action of the skin, laxatives to relieve the congested condition of the kidneys, and non-irritating diuretics, such as acetate of potash and digitalis, are indicated. Nitroglycerine is valuable where the action of the heart at any time becomes suddenly feeble and irregular.

Original Article.

GAVAGE IN INFANTS.

BY JOHN W. BARTOL, M.D., BOSTON,
Assistant Physician to Infants' Hospital.

THE attention of the profession was called long since to the value of tube feeding in patients (infant or adult) suffering with forms of disease attended by obstruction to the passage of food into the stomach; but it is perhaps not so generally recognized that there are frequently, among infant patients, cases free from such obstruction in which resort to this procedure will be followed by gratifying results.

When a child *can* but will not swallow its food, we are apt to accept the condition as a decree of nature and console ourselves with the belief that the patient is better after all without the food. That such refusal is, however, not rarely the result of some slight discomfort attending the taking of food, or of a whim caused by the disordered *morale* of the child, and not dependent on a seriously disabled condition of the digestive organs, is certainly indicated by the few cases here reported in support of such assertion.

In other words, the infant, like the adult, often has in its morbid conditions of body or mind a positive distaste for nourishment of any kind; but, unlike the adult, is not able to call to its aid the power of will so often essential for the obedient execution of the physician's mandates. It is obviously our duty, then, in appropriate cases, to feed him if need be directly against his will.

Let no one imagine that I am thus advocating wholesale and indiscriminate "forced-feeding" of sick children, or asking anybody to disregard the evident indications of a given case: the point simply being, not to disregard the possibility of satisfactory assimilation of much-needed nourishment in spite of obstinate refusal to receive such nourishment in the ordinary manner.

Furthermore, the method not only offers the advantage of administering food of fixed amount and definite

proportions at appropriately regulated intervals, but also furnishes a ready means of exhibiting, at the same time, such medicine as may be desirable.

The indications for instituting this method of feeding need no extensive mention, but the following three selected cases from the wards of the Summer Hospital at Rainsford Island, certainly show that it has a varied application.

CASE I was a male infant, eleven months old, who had previously been under treatment for congenital syphilis in the wards and out-patient department of the Infants' Hospital. He had been lost sight of for some months, but in the latter part of July was sent to Rainsford with the history of ten to twelve dejections daily, and of taking his food badly. It was further elicited that the inunction cure had been persisted in without medical supervision for four months.

The physical examination showed nothing of material interest except general delayed development. He was fairly well nourished. After admission to the wards and cessation of the inunctions there was no diarrhea; but he persistently refused to take a satisfactory quantity of food, and consequently as persistently lost weight (seven ounces in five days). He was accordingly discharged with the idea that he would probably take his food better in the home surroundings.

To quiet a possible suggestion that it may have been the taste of the food that caused him to rebel, it should be noted that, although at first he was given a Pasteurized modification, this was later changed to non-Pasteurized whole milk, without effect.

Ten days after discharge he re-appeared, and according to accounts had been vomiting and defecating almost constantly since going home. It was found that he had continued to lose weight at the rate of nine ounces in ten days, and now, at the age of eleven and a half months weighed 12 pounds 11 ounces.

The diarrhea proved not to be an important factor in his condition, but he at once resumed his old tactics of refusing food, and on the fourth day had dropped to a total food consumption of 20 ounces daily (the normal average being about 40 ounces), with a loss in weight of six ounces. During all this time he seemed perfectly well and happy but simply would not take his food.

He was then put on alternate feedings by tube, with the immediate effect of raising his total for the following twenty-four hours to 32 ounces. For the next month, by aid of the supplementary feedings, he maintained a daily average of 34 ounces; and in this time, his weight, which had steadily fallen for at least three weeks previous to beginning the treatment, increased one pound.

The day before his discharge tube feedings were entirely omitted, and the total amount of food taken fell from 32½ ounces to 21½ ounces, and his weight dropped 1½ ounces. But as cool weather came on, he began to take his food better; and I have lately learned that he is now thriving.

CASE II was a male infant, four months old, who entered the hospital with fermental diarrhea complicated by a moderate degree of colitis. The treatment of the latter condition proved somewhat prolonged and does not concern us now. The important consideration was to get him to take nourishment enough to keep from falling seriously behind in vitality; for in the first 17 days he averaged only 14 ounces daily, when he should have taken about 30 ounces, and his weight dropped from 10 pounds 1½ ounces to 8 pounds 9½ ounces, a loss of 1½ pounds.

He was accordingly put on alternate feedings by tube, which brought his total for the next twenty-four hours to 20½ ounces (from 14 ounces), with an immediate gain in weight of 2½ ounces.

For the ensuing 26 days, that is, the period of supplementary feedings, his daily average was 27 ounces as against 14 ounces, and his total gain in weight one pound one ounce.

The intestinal disorder having yielded to treatment, tube

feedings were omitted, and, although his average food-consumption and weight-gain showed an immediate drop, the advantage gained was permanent, and he was discharged in first-rate condition, weighing, in spite of his initial loss of $1\frac{1}{2}$ pounds, three-quarters of a pound more than at entrance.

CASE III is in some respects the most satisfactory of the three chosen for report, because, while in the others the procedure served to keep the system much nearer par. and thus established normal gain much earlier and on a more rapidly advancing basis than could otherwise have been done, in this case the prognosis *quoad vitam* was distinctly gloomy, and the necessity for quickly turning a corner very evident.

The patient was a female infant, one and a half years old. Her previous history was not obtained, but at entrance she had a temperature of 103° , with signs of well-developed broncho-pneumonia. There was evident delirium, and she seemed entirely unconscious of her surroundings, throwing herself about the crib regardless of consequences.

Without further reference to the course of the disease, it is sufficient to say that the problem which soon presented itself was how to get proper food and stimulation into her. From the first what milk she took voluntarily was evidently simply to satisfy her thirst; and at the end of the first week she was taking only twelve to fifteen ounces daily, and much of that under protest and at expense of provoking exhausting spasms of coughing. Put upon tube feedings, alternating with others from a cup, she rapidly increased her average; and when it was considered safe to begin regular weighing, which so far had been omitted on account of her serious condition, she was found to be steadily gaining.

To spare further details, I will simply add, that, partly on account of her disinclination to take food, partly because of the obstinacy of the spasm of coughing provoked by drinking, the tube feedings, which were attended by much less irritation, were continued to a greater or less extent for one month; and that in the 21 days after weighing was begun she gained one pound four ounces.

The progress thus so satisfactorily initiated continued until her discharge, one month later, during which period she made a further gain of two pounds five ounces.

Of the *modus operandi* I need hardly speak, except to remind those who happen never to have followed the procedure, of its great simplicity.

The entire apparatus consists of a soft-rubber catheter coupled to a small funnel by a combination of rubber and glass tubing. Of course, the largest catheter that can be comfortably passed gives quickest results. In most cases I found the nose by far the better route, but in at least one case the milk ran much better when the catheter was passed through the mouth. For the nasal cases a No. 6 catheter was generally found best, and for the mouth Nos. 10 to 12.

Feedings were given with patient lying in the crib, firmly rolled up in a sheet to keep the arms and legs from interfering. The right and left nostrils were taken alternately, and in no instance was there notable irritation of the mucous membrane, although in one case four tube feedings daily were given for nearly a month. There is almost no danger of passing the tube into the larynx, but a sufficient check against this, is the sound of the voice in the short fit of crying that is sure to be excited by the procedure. The arrival of the end of the tube in the stomach is heralded by the escape of a small amount of gas. The food may then be poured in at once, disregarding the small column of air in the catheter.

The tube during withdrawal should be tightly pinched to prevent the milk from trickling over the pharyngeal wall and exciting the reflex. Coughing

and crying delay, but do not prevent, the passage of the food, which flows at least during the inspiratory interval. If there is any indication for it, the feeding should be preceded by washing out the stomach.

Catheters and tubing should be boiled daily and kept between feedings, after thorough washing, in boric-acid solution.

There is an important class of cases which is not illustrated here by any specific instance because there happened to be no striking example in the wards, but which deserves emphatic mention before closing this paper. I refer to a certain type of obstinate vomiting, where the child takes food readily enough, but is unable to retain it even in small amounts. It will often be found in these cases that the reflex vomiting is much less likely to be excited by the passage of the tube, than by the food itself taken in the natural way; and thus patients that give every promise of steadily advancing failure may be tided over until a slight gain in tone enables them to resume the normal habit.

Clinical Department.

A CASE OF CONGENITAL MALARIA.

BY KENELM WINSLOW, M.D., NEWTON, MASS.,
Assistant Professor of Comparative Therapeutics, Harvard University;
Visiting Surgeon, Newton Hospital.

MALE child. Family history negative, except that mother had quotidian malaria of a severe type for two weeks preceding birth of patient. The malaria was untreated by her physicians who deemed such treatment unwise during pregnancy. The malaria continued until parturition, and then ceased. The child weighed seven pounds at birth, was well developed, and appeared sound, except for an umbilical hernia.

The writer saw the baby for the first time, December 3, 1896, when the child was ten weeks old, the case having been kindly referred to him by Dr. F. H. Davenport, of Boston.

The child did not flourish on his mother's milk; had colic and vomiting. Most of the artificial foods had been tried for a few days each in turn, and Meig's mixture had been in use for a short time previous to my visit. The baby appeared to improve with all the foods at first, and then began to vomit, had colic and refused the food altogether. Considerable mucus had been evacuated from the bowels (which were generally constipated) and vomited from the stomach. In addition to these symptoms the child slept little, cried a great deal, was continually moving, and had cold hands and feet.

Physical examination showed the patient to be much emaciated, pale and weak. Chest and abdomen negative, except hernia. Muscles of the limbs and neck rigid; head slightly retracted; and child cries out on handling.

This child was fed for a few days succeeding my visit on whey and beef-broth, when the patient had a severe convulsion in the writer's presence, characterized by muscular rigidity, unconsciousness, clonic spasms and strabismus, followed by a period of muscular relaxation and stupor. It then developed that these attacks had occurred daily since birth, and had been unrecognized as convulsions. They were always preceded by prolonged crying.

On this day, December 7, 1896, the convulsions were more continuous and severe than ever before. Three grains of chloral and five grains of sodium bromide were given by rectum, and Dr. T. M. Rotch was called in consultation. Dr. Rotch made a provisional diagnosis of inanition from indigestion, which might well have followed the injudicious method of feeding. The child was so exceedingly ill at this time that the prognosis was doubtful. The question of malaria was suggested by the family, but, as the temperature had been normal and no periodicity of the symptoms had been observed, the matter was left in abeyance.

Dr. Rotch recommended Walker-Gordon-Laboratory milk of the following composition:

Albumin	0.5%
Fat	2.0
Sugar	6.0

One-half ounce every hour.

The child improved slightly for three days, and then began again to have continuous convulsions, so that bromide and chloral were resorted to for several days.

The blood was examined on December 10th, and the plasmodia malarie were found in abundance. The child was given one grain of quinine by the rectum in enema twice daily, and the convulsions ceased from this time, but muscular rigidity, sleeplessness, colic, constipation and restlessness persisted.

Dr. Rotch was informed of the result of the blood examination, and advised one-half grain of quinine twice daily by suppository. The suppositories were so frequently expelled that it was necessary to resort to enemata again.

December 15th. Milk altered as follows:

Albumin	0.75%
Fat	3.00
Sugar	6.50

One and one-half ounces every hour and a half.

December 19th. Blood-count showed normal number of red corpuscles, and examination also exhibited plasmodia present.

January 1, 1897. Milk increased as follows:

Albumin	1.00%
Fat	3.50
Sugar	6.50

January 2d. Plasmodia present in the blood. The Walker-Gordon-Laboratory milk had been taken and retained admirably; but the symptoms did not improve, except in relation to vomiting and convulsions.

About this time I tried to substitute a home-made milk mixture for the laboratory milk, but it caused vomiting and convulsions after a few days. Analysis of my mixture showed seven per cent. of fat, which explained the result.

Since the patient did not improve nor gain in weight after a month's treatment with quinine, I advised the removal of the child to a non-malarial place. The baby was taken to a relative in Danvers, and began to improve immediately, gaining one-half pound a week. The quinine was stopped after the first week of absence from home, and one-fifth of a drop of Fowler's solution substituted, three times a day. To exhibit the sensitiveness of the child in regard to its milk, the formula was increased in strength, January 24th, as follows:

Albumin	from 1.00 to 1.25%
Fat	from 3.50 to 4.00
Sugar	from 6.50 to 7.00

Two ounces every two hours.

The patient vomited several days, owing to this slight increase in the quantities of the various nutrients, but did not have convulsions. Since this time there has been an uninterrupted recovery.

February 25th. Blood examination showed absence of plasmodia.

March 1st. The baby weighed thirteen pounds and was taking the following milk mixture:

Albumin	1.50%
Fat	4.00
Sugar	7.00

Three ounces every two and one-half hours.

The case is of interest because of the rarity of congenital malaria, and in illustrating the value and necessity of blood examinations for diagnosis and exact methods of feeding in order to proportion the strength of the food to that of the patient's digestion. The plasmodia were probably conveyed directly by means of the fetal circulation, although there is a possibility of infection by the mother's milk. Since the symptoms were the same up to the time that the diagnosis of malaria was made, it is sufficiently evident that the disease existed from birth.

A CASE OF ACHILLODYNIA DUE TO AN EXOSTOSIS OF THE OS CALCIS, ASSOCIATED WITH AN INTERESTING FORM OF BURSITIS.

BY JOEL E. GOLDTHWAIT, M.D., BOSTON.

THE following case is reported in order to put on record another case of achillodynia, due to the presence of an exostosis under the tendon Achilles, and also, because of the condition of the bursal sac found at the time of the operation, which probably explains, in part, the irregular attacks of pain which are described in such cases.

The patient, H. F., twenty years of age, has for several years been troubled with his feet, having suffered considerably with pain about the heels. During this time he has been unable to work with any degree of regularity, a few days of activity being followed by so much pain and discomfort that it was impossible for him to be about. The pain has usually come on suddenly, and has been chiefly referred to the heels, with some, of late, across the front of the feet.

The patient came to the Orthopedic Clinic at the Carney Hospital several months ago, and when first seen there was a marked flat-foot in both feet, and all motions were accompanied by pain. Behind both heels there was some acute swelling, with a distinct increase in the surface temperature. There was no fluctuation or evidence of anything more than an inflammation of the sheath of the tendo-Achillis. Under rest and bandaging the pain and swelling disappeared, and by the use of foot-plates the flat-foot was entirely corrected.

In a short time, however, after the patient commenced to go about, the pain and swelling in the heels returned. This was again relieved by rest and bandaging, but was followed by relapse as soon as the feet were used. This was repeated several times, until finally a skiagraph of the feet was taken which showed plainly the presence of the tubercle under the

tendo-Achillis. Recognizing this as the probable cause of the heel symptoms, an operation was performed and the tubercle of bone removed. During the operation, when the tendon Achillis was drawn aside, a large bursa was opened, the lining membrane of which had become so much hypertrophied as to be thrown up into folds, forming fringes which undoubtedly became pinched between the tendon and the bone during motion. This undoubtedly caused the acute symptoms, exactly the same as the synovial fringes in the chronic (non-tubercular) inflammations of the knee-joint get caught between the bones, locking the joint and cause acute pain and swelling.

Some of the fringes in this case were fully a half an inch long, and during the operation it was perfectly easy to demonstrate the way in which these folds caught and became pinched between the tendon and the bone during motion.

The presence of exostoses under the tendon in such cases has been fully described by Albert, Röseler, Schüller, Brackett and Wiesinger; but the condition of the bursal sac described above has not, so far as I am aware, been described before. This condition is probably not rare, as the normal bursa must enlarge as the result of the increased irritation due to the presence of the exostosis or bony tubercle; and with this enlargement, or chronic inflammation, the lining of the sac is, in all probability, usually thrown into folds, as is true of synovial membranes elsewhere.

The only suggestion to be made in regard to the treatment of such cases, is not only to remove the bony protuberance, but also to carefully remove the bursa as well.

Medical Progress.

REPORT ON PROGRESS IN GYNECOLOGY.

BY EDWARD REYNOLDS, M.D.

SHORTENING THE SACRO-UTERINE LIGAMENTS AND RETROVERSION.

GOTTSCALK¹ writes in advocacy of another vaginal method of treatment of movable retroversions. He believes that the cause of the retro-deviation is to be found in relaxation of the sacro-uterine ligaments, and holds that shortening these ligaments is therefore the most reasonable method of treatment. He replaces the uterus and cuts through the posterior fornix in the median line, opens Douglas's fossa, and holds the wound open with temporary stitches inserted between the vaginal and perineal edges. If adhesions are found, they are separated at this stage of the operation, and the uterus is then replaced. An assistant holds the wound open by traction on the temporary ligatures while the operator makes one utero-sacral tense with his forefinger, and then under the guidance of the eye transfixes it from above downwards with a sharp aneurism needle. The other end of the same suture is then passed through the substance of the cervix by a sharp needle just below the level of the os internum. When this suture is tied, the cervix is drawn strongly backward by the tension of the shortened utero-sacral. The same procedure is then performed upon the opposite side, and the operation is completed. The wound is drained by a small strip of gauze, and al-

lowed to heal by granulation. The patient is made to lie upon her side or abdomen, and is kept in bed seven days, the uterus being held in position by an internal tamponade. Gottschalk has performed this operation twice, both times with satisfactory results.

NEW METHOD OF VAGINAL FIXATION OF THE UTERUS.

Kiefer² adds still another to the many methods which have of late been proposed. In his operation the bladder is separated from the uterus, and two fingers are introduced into the peritoneal cavity. Under the direction of the fingers the abdominal wall is punctured with a long, sharp, curved artery-needle carrying a ligature of catgut or silkworm-gut. The end of this suture is caught on the outside; the other end of the suture is then passed around the round ligament and out again through the abdominal wall by the same instrument. The other ligament is treated in the same way, and the vaginal wound closed. The advantages of the operation are, of course, found in the fair mobility which is permitted to the uterus, thus rendering interference with pregnancy unlikely, and in the absence of the abdominal scar. The author believes that in this method, puncture of the intestines is practically impossible.

ADMINISTRATION OF OVARIAN TISSUE DURING THE ARTIFICIAL MENOPAUSE.

Chrobak³ has been experimenting for some years upon the effect of the internal administration of the ovarian tissue of cows upon the modification of the nervous symptoms following the removal of the ovaries in women. In the first case, the fresh ovaries of calves were given, with a negative result. In seven other cases the ovaries of mature cows were washed with ether and alcohol, dried, powdered, and made into tablets, each of which was equal to three grains of ovarian tissue. Two to five such tablets were given daily. Of the seven cases, one was passing through the normal climacteric, while in the other six both ovaries had been removed. In two patients the climacteric disturbances ceased entirely after twelve tablets had been taken; in the third, after twenty tablets, the frequency was reduced one-half; in the fourth, the frequency was reduced two-thirds, but was re-established at its old vigor whenever the tablets were omitted. The author believes that the remedy promises well.

Laudan,⁴ after experiments similar to Chrobak's, and suggested by his, reaches essentially the same conclusions, namely, that the remedy produces no evil results, that it probably improves the condition of the patients, and should be carefully observed in some further series of cases.

TRANSPLANTATION OF THE OVARY.

Knauer⁵ makes a preliminary report on the transplantation of the ovaries of rabbits, the operation being done under an anesthetic and the strictest aseptic precautions. Three rabbits were operated upon, the ovaries being tied off with silk, and removed essentially without handling. All the ovaries but one were then stitched to the uterine cornua with silk, care being taken not to include ovarian tissue in the

⁴ Berliner klin. Wochenschrift, 1896, No. 25.

⁵ Loc. cit.

¹ Centralblatt für Gynäkologie, 1896, No. 16.

stitches. In the first experiment, one ovary was placed a little to one side of the abdominal wound, between the fascia and muscle, and the wound was then closed with buried sutures. Two of the rabbits were killed, the other died several months after the operation. All the ovaries were fairly well nourished and functionally active, that which had been placed between the layers of the abdominal wall being the most atrophied, that is, to about one-third of its former size. He makes the following deductions: (1) the ovaries of rabbits may be transplanted to a distance from their natural sites; (2) the attachment may be to peritoneum or muscular tissue; (3) the transplanted ovaries are nourished by new-formed vessels and remain functionally active, developing Graafian follicles which ripen and in all probability discharge their ova.

The author next intends to transplant the ovaries of other animals and to transplant them from one individual to another, with the special object of noting whether fecundation follows the operation or not.

Moud,⁶ after observations made by a closely similar method, attained about the same results.

THE TREATMENT OF FIBROIDS BY THYROID EXTRACT.

Jouin,⁷ in the course of treatment of obesity by the administration of thyroid extract, noticed a large uterine fibroid extending above the umbilicus, become rapidly lessened in size to about one-fourth of its former dimensions. He afterwards treated 17 cases by this method. In 12 cases marked hemorrhages ceased, and the size of the tumor diminished; two other tumors were decreased decidedly; two slightly, if at all; and one not at all. The author believes that in addition to the reduction of size which he noticed, the pain, pressure, weakness and hemorrhage due to the affection was certainly lessened.

THE CURE OF SEPTIC PELVIC DISEASE IN WOMEN.

Henrotin⁸ has a long article in support of the conservative vaginal operations with which his name is prominently associated. After a discussion of the value of and indications for curettage, an earnest plea in support of the coming recrudescence of a belief in the frequency of pelvic cellulitis, and a statement of his own belief that the inflammatory masses under consideration may be originated by an infection of the ovaries, he comes to the consideration of the operative treatment. He condemns a too early removal of the appendages, but lauds heartily his procedure of incising and draining the organ which is the source of the infection at the earliest possible moment, and re-describes the technique in detail. The first step in the operation should always be a thorough and efficient curetting, isolating and packing of the uterus. The posterior vaginal fornix should then be incised along the posterior face of the cervix; and from the centre of this a second incision should be extended backward along the median line so far as the rectum permits. The retro-uterine connective tissue should then be drawn up by the fingers, always working close to the uterine surface, the cervix being held steady by moderate downward traction with a hook or tenaculum. If pus is detected in the connective tissue before the

peritoneum is opened, it should be followed up by tearing dissection with the fingers into the centre of the mass which is felt to be present. If pus cavities to correspond with all that has been felt on bimanual examination are opened in this manner, and the operator is certain that he has not opened the general cavity, they should be drained and the operation concluded. If the peritoneum is reached without the opening of pus cavities, the general cavity should be opened at once on the ground that even the traction on the uterus may rupture pus sacs; that if this is done before drainage of Douglas's fossa has been instituted, it will probably result fatally; if afterwards, there is but slight danger. The hands and instruments are then again thoroughly cleansed and the pelvis explored bimanually, the examining finger being, however, in Douglas's fossa instead of in the posterior fornix of the vagina. Whatever masses are felt should be dissected apart with the fingers and drained by the insertion of gauze. Even if fluid is not found, the opening a path into the centre of an exudate may entirely remove the symptoms; and though the operation may seem blind, the majority of the patients are cured. The duration of the drainage after the operation must be determined by the character of the fluid discharged, being guided by ordinary surgical principles. Hemorrhage may be quite free, but has always heretofore been controlled by the gauze packings. The author quotes a number of cases as types of those with which he has met.

SADDLES AND POSTURES FOR WOMEN ON THE WHEEL.

Dickinson⁹ has an article admirably illustrated with photographs of nude and costumed models, and of skeletons, each position being shown by a series of three photographs, and, in addition, comparisons of the bicycle posture with that of the sewing machine and of the side-saddle are afforded by additional series of photographs. The position advocated is that in which the centre of the hip-joint is directly over the centre of the pedal when at its highest or lowest point, when the height of the saddle is such that with the pedal at the lowest point the knee is slightly bent and the ankle somewhat straightened, while the height of the handle-bar flexes the elbow slightly and keeps the wrists well extended. The various makes of saddle which have been upon the market for the past year are illustrated by cuts, the type of saddles represented by the Messenger, Garford, Hunt and the Reform Wheeler being considered by the author the most generally useful. The Christie, Duplex, Empress and Common-sense are considered well adapted to some individuals.

HYSTERECTOMY FOR FIBROID, CARCINOMA, AND IN PREGNANCY, AFTER LIGATION OF THE ANTERIOR TRUNK OF THE ILIAC ARTERY.

Polk.¹⁰ The various bloodless methods which have been proposed for the radical removal of extensive uterine carcinoma, or for the difficult extirpation of fibroids are added to by this paper of Polk's. His operation differs from those of Pryor and Kelly chiefly in the method by which he reaches the origin of the anterior trunk of the internal iliac artery which, like other operators, he believes to be the best point

⁶ Mitleiner med. Wochenschrift, 1896, No. 36.

⁸ American Gynecological and Obstetrical Journal, 1896, vol. viii, No. 6.

⁹ Loc. cit., 1896, vol. viii, No. 6.

¹⁰ Loc. cit., July 1896, vol. ix, No. 1.

for the application of the ligature. He recommends that the ovarian vessels and round ligaments should be tied and separated as in any other hysterectomy; the cut surface of the broad ligament at the sides of the pelvis should then be lifted up and opened. The posterior portion of the cut surface should be drawn back and the peritoneum separated from the pelvic wall by the fingers and handle of a scalpel inserted through the cut, until the finger reaches the internal iliac artery. This should then be followed by touch to its bifurcation; the anterior trunk is then separated, isolated and tied. In about one-fourth of all the cases the obturator artery gives off the uterine as well as the two lower vesical arteries, and in such cases, the obturator springs from the posterior trunk but then leads forward directly below the anterior trunk, where it is easily felt and can be included in the same ligature. In case of doubt, this divergence from the normal can be ascertained by tracing the uterine artery. The operator should restrict himself to the fingers and the handle of the scalpel in order to avoid the danger of wounding a vein. When these vessels have been tied upon both sides there is no possibility of bleeding in the removal of the genital organs, except from the incision of the posterior vaginal wall which, in many people, is fed by branches from both the superior and middle hemorrhoidal vessels and may, therefore, require separate ligation at the time of their division, since the superior hemorrhoidal is not controlled by ligation of the anterior trunk of the internal iliac. If the operation is undertaken for the removal of a cancer, the ureters should be dissected from their beds as soon as the vessels have been ligated. This may be accomplished either by taking up the ureters at their origin from the bladder and dissecting them off from below upwards, or by finding them as they cross the common iliac artery at the brim of the pelvis and making a similar dissection downwards.

AN ELECTRODE FOR THE REMOVAL OF LIGATURES.

Cleveland¹¹ describes an electrode for the removal of ligatures in vaginal hysterectomy. He believes that it is of great benefit to remove the sutures early, and has been much pleased with the instrument here described. It is a loop of platinum attached to copper wires, which is tied in with the silk ligature. At the end of thirty-six hours, the wires are attached to a three-cell storage battery, the current burns through the silk and ligature and electrode are removed together.

NEPHROTOMY FOR PYELONEPHROSIS.

Tally¹² reports a well-studied case of pyelonephrosis during pregnancy originating from catheterization during the previous puerperium.

Norris¹³ reports a similar case treated at first by attempts at catheterization of the ureter with the idea of washing out the pelvis of the kidney; and later, by lumbar incision. The author failed to make a success of the catheterization of the ureters, and each attempt only aggravated the symptoms. After the incision, it was found that each attempt to remove the drainage-tube was followed by severe pain. This was believed to be due to the presence of an inflammatory thickening of the ureter which rendered it practically impervious. A bougie was therefore passed from the lum-

bar wound through the bladder to the ureter every third day, and after three weeks of this treatment, the drainage-tube was removed without ill result. This condition of the ureter probably explains the failure of the attempts at catheterization, as the author had repeatedly been successful in previous catheterizations of the ureters for disease of other types.

NEPHRECTOMY FOR TUBERCULOSIS OF THE KIDNEY.

Noble¹⁴ reports a nephrectomy in which a positive diagnosis of large tubercular tumor of the left kidney was made by repeated catheterizations of the ureters, which at the same time showed the condition of the right kidney to be such as would warrant the nephrectomy. He concludes that systematic examinations of the urine should be made in all cases of supposed renal colic, and supplemented by a systematic study of the separated urines obtained through the ureteral catheters.

TREATMENT OF PERITONEAL INFECTION.

Pichevin¹⁵ discusses the relative advantages of flushing out the abdomen or wiping the peritoneum with dry gauze after the entrance of pus into the abdominal cavity. He considers that the question of the superiority of the one to the other at the time of the accident has not yet been settled, but strongly advocates the re-opening of the abdomen and free washing out of this cavity with a borated and then a normal salt solution, when the operation is followed by the symptoms of suppurative peritonitis. He relates a case in which he used the dry sponge method after rupturing a sac in the cavity. Two days later, the abdomen was tympanitic, pulse 120, small and wiry, respiration 50, tongue dry, thirst excessive, no vomiting. Drainage had of course been inserted, and, on examining the serous fluid which the drain was removing, no micro-organisms were found, from which the author diagnosed the beginning of an intestinal occlusion. The drainage was removed, cathartics given, and the patient recovered. He says that intestinal occlusion following operation often simulates peritonitis. It may be caused by pathological germs in the perineal cavity, but can also occur as the result of operation, or from paresis of the intestine. A bacteriological examination will determine with certainty whether the cause is sepsis or not. Catharsis should be used in all cases, but more especially when there is no peritoneal infection. In occlusion from compression, the effect is remarkably valuable. In true peritoneal infection, catharsis is not sufficient. It must be supplemented by intravenous or subcutaneous injections of salt solution and, if necessary, the flushing out of the peritoneum either through the drainage tract or by re-opening the abdomen.

THE EIGHTH INTERNATIONAL CONGRESS OF PHARMACY will be held at Brussels from August 14th to 19th inclusive. The proceedings of the Congress are designed to interest all working in pharmacy or such allied branches of knowledge as toxicology, pharmaceutical chemistry, bacteriology in relation to pharmacy, and the legal position of the dispenser and the prescribing physician. There will be prizes given for essays contributing to scientific or practical knowledge on any of these points.

Reports of Societies.

ANNUAL MEETING OF THE AMERICAN SURGICAL ASSOCIATION.

WASHINGTON, MAY 4, 5, 6, 1897.

FIRST DAY. — TUESDAY.

THE meeting was called to order at 10 o'clock, the President, JOHN COLLINS WARREN, in the chair.

The President read a paper entitled

THE INFLUENCE OF ANESTHESIA ON THE SURGERY OF THE NINETEENTH CENTURY.¹

DR. J. HOMANS, of Boston, read a paper entitled

THE INDICATIONS FOR THE TECHNIQUE OF HYSTERECTOMY.

He divided the indications for Hysterectomy into seven headings: (1) in intractable, often-recurring hemorrhage without discovered fibroid, or malignant disease when all the usual remedies including curetting have failed; (2) in all cases of malignant disease when the operation is possible without permanent injury to the bladder or bowels; (3) under certain circumstances in cases of fibroid tumor; (4) in cases of uncontrollable complete prolapse, particularly after the change of life, when pessaries and all the usual operations have failed; (5) in cases of incurable chronic inversion; (6) in cases of infection when the removal of the Fallopian tubes affected with salpingitis has not cured the patient; (7) to cure puerperal sepsis where the diagnosis is as certain as it can be.

Dr. Homans then described two cases in detail, as examples of the first class. The first case was one of chronic hyperplastic endometritis, and the other one was where an undiscovered fibroid existed in the right cornu and gave rise from time to time to severe hemorrhage. He then described in detail the technique of hysterectomy, and stated that the technique for malignant fibroid disease of the uterus by the vaginal route is the same as for the removal of the non-malignant uterus, while the technique of the removal of the uterus on account of cancer will vary according to the type of the disease. Hysterectomy is indicated in cases of fibroid tumor which cannot be enucleated either from the inside or from the outside of the uterus. He then fully described the technique of abdominal hysterectomy, where it was decided to leave the neck and os. The author objected to the expression "the uterus and its appendages," and suggested instead, "the ovaries and their appendages," the ovaries being the reigning powers in the generative organs. The vagina may be wanting or the uterus may be wanting in cases of imperfect development, but their absence does not imply that of the ovaries, while if the latter are wanting, the other organs always are. In complete hysterectomy the os and the neck are separated from the vaginal wall before the abdominal dissection is begun.

The author then mentioned two cases illustrative of his sixth heading, both of which made good recoveries after operation. He advised the vaginal route in operation for the cure of puerperal sepsis, and suggested that a Jacques' self-retaining catheter should be put into the bladder for a few days after every hysterectomy.

DR. H. H. MUDD, of St. Louis, in discussing this paper, said that the technique of hysterectomy for fibroid tumors varied with the special indications of each case, and he considered that this operation for suppurative peri-uterine inflammations should be restricted to a very narrow field. The extension of carcinoma of the os occurs in two ways: first, along the vaginal tissue; and, second, into the broad ligament. Abdominal hysterectomy is probably the best in cases where the malignant growth begins in the body of the uterus. Most cases of malignant disease requiring hysterectomy originate in the os, and may be removed by the vaginal route when seen early. The author prefers to have the patient anesthetized upon the operating-table, so that as much time as possible may be saved. He is in favor of the Trendelenburg position, and advises that the abdominal incision be sufficiently large for rapid and accurate work. When the growth is soft and pliable, he suggests that it should be cleansed with a curette and sterilized water and wiped off with a gauze sponge; the firmer margins should be approximated by sutures. He described in detail the steps in the operation, and recommended that silk be used in securing the ovarian artery. He has discarded the use of iodoform gauze where it is brought in relation with the peritoneum, considering it dangerous.

DR. F. E. LANGE, of New York, stated that all working in the dark in these operations should be avoided, and considered hemorrhage and sepsis the two most important dangers. In some cases he has employed a vaginal incision, and in others a crucial incision above the symphysis pubis. But in some cases the fleshy portions do not offer sufficient resistance when brought together, particularly where the patient becomes pregnant after the operation, and has not been so previously. Sometimes it is necessary to use the apron of the large omentum to prevent the agglutination of the intestine. The para-vaginal and para-rectal incisions consist of the separation of all the soft parts alongside of the rectum, which the author has employed in some cases. The advantage is that the floor of the pelvis is more accessible and provision against infection is also greater, because the drainage takes place away from the peritoneal cavity.

DR. DUDLEY P. ALLEN described an operation which he has found to work very well in a number of these cases.

DR. ALBERT VANDER VEER, of Albany, agreed with Dr. Homans as to the places where hysterectomy was advisable. He was in favor of the supra-vaginal or abdominal method in cases where the vagina was comparatively normal, and the cervix in a healthy condition. It gave the operator an opportunity to remove adhesions and to thoroughly explore the pelvis and its contents. He preferred the vaginal route if a cystocele or rectocele or prolapse of the ovaries be present. He laid great stress upon the fact that much more could be done for these cases if they were only seen much earlier and promptly diagnosed and treated. In cases of carcinoma confined to the uterus where microscopical examination confirms the suspected symptoms and indications, he advised operation. The surgical route should be by way of the vagina when the uterus is not too large from invasion of the body by the disease, and when no pregnancy beyond the third month complicates it; but he was not in favor of operation in all cases of fibroid, as

¹ See Journal, page 432, May 6, 1897.

many patients are not inconvenienced by their existence. He strongly urged a free abdominal incision in all cases of pan-hysterectomy, and urged that no more of the pelvic organs should be removed than is actually necessary.

DR. J. WILLIAM WHITE, of Philadelphia, read a paper entitled

THE X-RAYS IN SURGERY.

The author dealt with the subject under three headings: (1) in its relation to foreign bodies; (2) fractures and dislocations; (3) diseases of bones and joints. He stated that bullets in the thoracic cavity can be located with reasonable accuracy in the trachea, bronchi, lungs and pleura, and that their recognition in the cranial cavity is usually an easy matter. Bodies can be very satisfactorily detected in the esophagus, but rubber tubes in the pleural cavity seem to be translucent to the rays and cannot invariably be detected. The taking of skiagraphs with the patient in several different positions in the case of foreign bodies in the pelvic cavity is of service. He divided fractures of the skull, as regards their recognition into three kinds: fracture of the inner table, fracture of the outer table, fracture of the base. Up to the present the first two have only been successfully recognized. The author predicted great help in the future from skiagraphy in diagnosing obscure cases of fracture of the sternum, scapula, clavicle, and pelvic bones. Skiagraphing the ribs is somewhat difficult on account of the respiratory movements, but this can be overcome by restricting the movements with a fixed dressing. Close fibrous union in cases of ununited fracture does not prevent its demonstration accurately, and the limitation of motion in cases of old fractures has been readily explained by the skiagraph.

The author gave it as his opinion that a patient has not the right at the present time to demand the taking of a skiagraph in cases of fracture, and thought that in this connection much trouble would result in the near future in a medico-legal way. He said there was no doubt that these pictures had done much towards aiding in the diagnosis of diseases of the bones and joints, but believed that the fluoscopes would be more useful than the skiagraph in cases of cardiac disease, on account of the constant motion. He mentioned that no rule can be laid down as to the time of exposure, as many things cause this to vary. Vesical calculi are more difficult to skiagraph than renal calculi, on account of the supra-position of the pelvic bone; and the urethral stone has not at the present time been seen clinically. The author has done some work with the rays in connection with cases of cancer, but as yet could not make any report.

DR. W. W. KEEN, of Philadelphia, referred to the medico-legal importance of the x-rays, and illustrated this by the history of a case.

DR. CHARLES B. NANCREDE, of Ann Arbor, urged that several pictures should be taken in different positions before one could feel safe in using the results for diagnostic purposes and demonstrated how the fluoscopes has in some cases succeeded better than the skiagraph. He stated that an expensive apparatus is not at all necessary for skiagraphic work, and that an expenditure of fifty dollars was sufficient for all purposes.

DR. G. R. FOWLER, of Brooklyn, agreed with Dr. Nancrede as to the importance of taking a number of

pictures in various positions, and also as to the fluoscopes being at times better than the skiagraph.

DR. M. H. RICHARDSON, of Boston, showed a large number of skiagraphs, and laid great stress upon their medico-legal importance, giving it as his opinion that many suits for malpractice would result from their use.

DR. WILLIAMS also showed a number of skiagraphs and an instrument for detecting calculi in the bladder.

DR. CHRISTIAN FENGER, of Chicago, mentioned a case in which the soft parts of the scalp died after exposure to the x-rays in the attempt to locate a bullet in the cranium, and attributed this result to too long an exposure.

SECOND DAY. — WEDNESDAY.

DR. DEFORREST WILLARD, of Philadelphia, showed a large number of skiagraphs and explained each. Some of them were of special interest, and particularly those taken of women with all the clothing on.

DR. EDMOND SOUCHON, of New Orleans, read a paper entitled

THE OPERATIVE TREATMENT OF IRREDUCIBLE DISLOCATIONS OF THE SHOULDER, RECENT OR OLD, SIMPLE OR COMPLICATED.

The writer considers all the forms and varieties of irreducible dislocation, and studies for each one the operation performed, the difficulties and complications after the operation, the results immediate, the results remote, and formulates the conclusions as to the advantages or disadvantages of each. The study is based on 140 operated cases. The profound silence of the text-books and also of special books on dislocations in regard to this most important subject renders this study most imperative and timely.

All irreducible dislocations, recent, simple or complicated with fracture that were operated by reduction or resection have given good results, with one exception, in which death does not seem to be due truly to the operation alone, but to a complication of shock, unusually severe at that.

Irreducible dislocations, old, simple and forward, operated upon by resection through an anterior incision, are the most frequent — 56 cases against 33 by arthrotomy and reduction. Results remote show a great mortality percentage in resections from injuries to the vessels, but this is avoidable with special care. The fatalities in reduction are due to sepsis, now preventable. The disadvantages of reductions are necrosis of the cartilages and of the head of the bone, calling later for sequestrotomies and resection. This is probably due to the greater dissections and denudations of the head and surgical neck necessary to reduce than to simply resect the head. Reduction is the more desirable operation of the two because it preserves the head and all the movements depending therefrom, but the necrotic consequences are serious drawbacks, as also ankylosis following sometimes the reduction. It should not be resorted to unless it can be done easily, without too extensive dissections, although it may be necessary to use hooks, levers and some curetting of the cup, as the cases reported show. The duration of the dislocation is immaterial; it is the condition of the parts that is all important. Recent irreducible dislocations have given as much, if not more, trouble to reduce than dislocations of months' standing.

The anterior incision is the route in all forward dislocations; almost all forward cases operated by the axillary route and the posterior incision have been unfavorable.

Cases reported as operated by subcutaneous section of fibrous bands, of tendons, of muscles and by osteotomy have given good results, but they are so few. It seems extraordinary that surgeons have not employed these methods oftener; perhaps they have, but, having failed, have not reported the cases. In considering the extent and the density of the tissues binding down the head and surgical neck to the surrounding parts, as reported by operators, it is a wonder that these methods should succeed except in very selected loose cases.

Irreducible dislocations, old and downward, four in number, have all been treated by the axillary incision with the resection, that is, removal of the fractured head more or less loose in the axilla, with favorable termination. In one case, however, the head was "pegged back" and reduced, with a good result. One downward dislocation (Desprès) was treated by osteoclasis; but it was a failure, no false joint forming. Yet there are cases on record of forward dislocation in which the bone was fractured near the head or through the surgical neck during efforts at reduction, and which yielded a fair enough result.

Irreducible dislocations, old and backward in the adult, have been reported twice. They were operated by resection, with a very ordinary result.

Irreducible dislocations, old, upward and operated, have not been found on record.

Irreducible dislocations, congenital, have been operated on several times; they were old, backward dislocations. Two cases were operated by reduction; one case died; the other had to have sequestra removed, and did well. Three cases were operated by resection, two with good results, the third one is not stated.

Irreducible old dislocations in young subjects or in old subjects are duly considered; also old dislocations double, that is, of both shoulders; also spontaneous or pathological and paralytic irreducible old dislocations.

The forms and varieties due to complications accompanying irreducible old dislocations are fully treated, and also the forms and varieties due to relapses or recurrences and to the sequels of the operations performed for irreducible dislocations and old, simple or complicated.

DR. J. EWING MEARS, of Philadelphia, suggested that the word "unreduced" should be used instead of "irreducible," and considered that the latter word could be applied when efforts at reduction are limited to manipulation, while the former could refer to dislocations which were not reduced even by operation. He advised an incision through the deltoid muscle in cases of recent dislocations of the shoulder which could not be reduced by manipulation, provided any operation was decided upon, and thought that disability and pain were the two most important factors for operative interference in old, unreduced dislocations. He suggested that massage and other like methods should be employed before an operation was suggested, and considered that any operation that would remove pressure and relieve pain was justifiable. He then referred at some length to an operation performed by himself in 1886 in attempting to form a false joint. Although the operation resulted in the relief from

the pain, it was demonstrated a year later at an autopsy that a false joint had not been formed, but union had taken place in such a manner as to pull the head of the bone off the axillary plexus.

DR. JOSEPH RANSOHOFF, of Cincinnati, did not think that it was often necessary to consider operative interference in recent cases of uncomplicated dislocations of the shoulder, that they were usually so easily reduced under anesthesia by manipulation, and that the degree of disability present in unreduced dislocations of long standing must decide the course of treatment to be followed. He considered pressure upon the vascular or nerve trunks a positive indication for operation. The operations suggested and practised for irreducible dislocations are four in number: first, subcutaneous division of the adhesions; second, subcutaneous osteotomy of the neck of the humerus; third, arthrotomy; and, fourth, resection; the last two being the most frequently indicated. A ready nidus for infection is afforded in old cases where a large cavity exists bounded by firm fibrous walls and lined with an imperfect serosa in the space where the head of the bone has been, and the earlier the interference the better the results.

In conclusion, the author summarized the present status of the question of operative interference in shoulder luxations, as follows:

(1) Immediate operative interference is indicated when the ordinary methods by manipulation under anesthesia have failed.

(2) In irreducible dislocations, operations should not be delayed until irremediable changes have taken place in the capsule and about the humeral head. In comparatively recent cases arthrotomy offers the best end-results.

(3) In old standing cases the conditions found must determine the choice between arthrotomy and resection.

(4) In unrecognized dislocations of long standing, a year or over, only grave compression symptoms must be recognized as indications for interference.

(5) Special attention must be given to the prevention of sepsis, since in a very large proportion of cases recorded, sepsis has been either the cause of death or by the destruction of the humeral head or obliteration of the joint cavity has frustrated the very object of the operation.

DR. J. J. OWENS, of Chicago, has only seen three cases of this kind, one of which was of the subcoracoid variety, in which it became necessary to cut into the joint, and finally to do a resection on account of necrosis setting in. In the second case, which was one of seven or eight weeks' standing, a resection had to be done, all other possible means of reduction having failed; and excellent results followed. In performing Kocher's method for reduction of a dislocation in the third case, the upper end of the bone gave way. The position was at once improved, and the pain at once disappeared. Daily movement of the bone was practised to prevent adhesion, and a very satisfactory result followed this sudden and accidental slip.

DR. JOHN B. ROBERTS, of Philadelphia, referred to a case in which much bruising and damage to the soft parts resulted from attempts at reduction, and necessitated postponement of the operation. Subsequently, after the operation was performed the patient died from shock and hemorrhage.

DR. L. McLANE TIFFANY, of Baltimore, recommended a free opening into the joint in cases of dislo-

cation of the shoulder-joint, putting them on the same basis as injuries to any other joint, and advised a resection in all cases where the head of the bone is firmly fixed in an abnormal position.

DR. SOUTHOX closed the discussion by speaking in favor of early operation in all cases before adhesions could form, and laid stress on the important part played by the deltoid muscle and a division of the filaments of the circumflex nerve in these cases. He also dwelt upon the significance of the after-treatment in these cases.

DR. E. H. BRADFORD, of Boston, read a paper on
TENDON ANASTOMOSIS.

He mentioned some of the good results that have followed the transference of muscles and tendons from a healthy to a paralyzed portion of the limb, and gave a number of instances in which this operation had been performed with excellent results. He illustrated diagrammatically a method of splitting the patella, and advocated in cases of spastic paralysis the lengthening of tendons and muscular fascia in the popliteal space, groin, etc. He laid stress upon the importance of testing a muscle electrically before transplanting it. The paper was illustrated with a large number of diagrams and drawings.

DR. JOHN B. ROBERTS, of Philadelphia, mentioned a case in which he had performed a similar operation with good results where paralysis of the extensors of the fingers existed.

DR. DEFORREST WILLARD, of Philadelphia, reported great improvement in several cases where similar methods had been employed.

DR. BRADFORD, in closing, merely mentioned a case of Dr. Dawbarn's in which good results followed transference of the insertion of the ligamentum patella by chiselling off the tubercle to which it is attached, crushing a portion of the tibia, and inserting the tubercle there.

DR. JOHN B. ROBERTS, of Philadelphia, read a paper on

THE SURGICAL TREATMENT OF SUPPURATIVE PERICARDITIS.

The author advocated, as he had since 1876, the treatment of pericardial effusions in the same manner as pleural effusions; and stated that paracentesis was insufficient to cure suppurative pericarditis. Incision and drainage were essential, and should be adopted as soon as diagnosis of pus in the pericardium was made. The diagnosis of the purulent character of the effusion was only determinable by exploratory puncture. This should be done at the upper part of the left xiphoid fossa, close to the top of the angle between the seventh cartilage and the xiphoid cartilage. Pericardotomy should then be done after resection of the fourth and fifth costal cartilages in the manner described by the author. The operation was believed to be novel in some of its details, though others have recommended, and operated by, various forms of resection. This method was devised to avoid injury of the left pleura, which is nearly always a complication in the ordinary methods of puncturing or incising the pericardium. As a rule, empyema is liable to occur as a sequel of pericardial puncture or incision in suppurative pericarditis. The prognosis is good in pericardotomy for pyo-pericardium. In a table of 26 collected cases 10 recoveries and 16 deaths were shown. This gave a

percentage of recovery of 38.4 +. Of the fatal cases at least nine were septic, and all the others who died had complicating lesions, such as pleuritis, or pulmonary, cardiac or renal lesions. The operation devised by Dr. Roberts consisted in raising a trap-door of the fourth and fifth costal cartilages and connecting soft parts, and using the tissues of the third interspace as a hinge. The internal mammary vessels and left pleura are thus exposed and pushed to the left, so as to leave the pericardium uncovered and accessible to operation.

DR. CHARLES B. PORTER, of Boston, reported one case successfully operated on, in which excellent health followed. He thinks the operation is indicated in all cases of purulent pericarditis based upon the results of cases already reported. In his opinion the ideal operation was, first, to avoid opening the pleural cavity; second, to open the pericardium opposite the point where the drainage will remain good after the sac has contracted; and, third, to secure permanent and free drainage. He then dwelt at some length upon the surgical anatomy of the parts, the steps of the operation, and the histories of a number of cases of reported recovery after free incision and drainage had been practised, illustrating his remarks with a number of illustrations.

DR. J. MCFADDEN GASTON, of Atlanta, Ga., stated that the conditions are more urgent in pericardial effusions than they are in pleural effusions, and consequently of late years more vigorous measures of internal treatment before mechanical evacuation is employed have been suggested. It has been urged that aspiration should be limited to serous effusion, and not to purulent collections. The author then detailed a large number of references to this subject by many authors in various publications during the past few years, and recommended the aspirator or the hypodermic syringe as the only means of testing the pericardial contents. Incision and drainage should be practised without delay when the collection is of a purulent character.

DR. DUDLEY P. ALLEN, of Cleveland, and DR. G. R. FOWLER, of Brooklyn, agreed with the foregoing speakers.

DR. ROBERTS closed the discussion, and thanked Dr. Porter for his report of the cases operated upon.

DR. S. H. WEEKS, of Portland, Me., read a paper entitled

REPORT OF A CASE OF REMOVAL OF THE GASSE- RIAN GANGLION.

The only apparent cause for neuralgia in this case was excessive mental work, the patient being a minister. The author described the operation as performed by himself, and stated that excellent results had followed, the limited amount of aphasia which had been present from the first having been gradually disappearing ever since.

DR. G. R. FOWLER, of Brooklyn, stated that he knew the patient upon whom Dr. Weeks had operated, and was aware of the intense suffering which preceded the operation. He was very glad to learn of the subsequent improvement.

Dr. Fowler also referred to the fact that the two cases of ligature of the common carotid and the external carotid which he performed in an effort to starve off the Gasserian ganglion, the details of which he reported to the Society last year, have remained free from a return of the disease up to the present time.

UNVEILING OF THE GROSS STATUE.

Wednesday afternoon, the Association, in conjunction with the Alumni Association of Jefferson College of Philadelphia, unveiled the statue of the late Samuel D. Gross.

The Address was delivered by DR. W. W. KEEN, of Philadelphia, who referred very feelingly to Dr. Gross, and gave a history of his life and of his services to the medical profession.

THIRD DAY. — THURSDAY.

DR. DUDLEY P. ALLEN, of Cleveland, read a paper entitled

THE ORIGIN OF APPENDICITIS.

He considered that there are three factors which must have some causative relation to this disease: first, a bend of the appendix itself; second, a stricture of the appendix on the proximal side of the inflamed portion; and, third, a great increase in thickening of that portion of the appendix distal to the point of flexure and stricture. The author dwelt at great length on the pathology of the disease, and illustrated his remarks with a number of drawings demonstrating the histology of the appendix, as well as with an actual appendix and also with a fetus showing the appendix *in situ*. In concluding his paper, the author summarized his conclusions as follows:

(1) In the descent of the cecum from the right hypochondriac to the right iliac fossa, the position of the appendix with relation to the cecum becomes changed.

(2) The bend thus produced may be sufficient to embarrass the passage of the contents of the appendix into the bowel.

(3) To empty the appendix an increased effort becomes necessary on the part of the muscular coats.

(4) The increased effort on the part of the muscle results in hypertrophy, amounting in the specimen presented to nearly five diameters.

(5) Increased pressure at the point of flexure produces irritation and inflammation, causing destruction of mucous membrane, and at length organic stricture.

(6) The hindrance to the escape of mucus produces the repeated attacks of pain resembling colic.

(7) When the escape of the contents of the appendix is no longer possible, either from the tightness of the stricture or because it is closed by a concretion too large to escape, distention of the distal portion may gradually go on to perforation, or, if the distention be rapid and extreme, to gangrene.

(8) In some cases the inflammatory process may not cause perforation, but terminate in destruction of the mucous coat, and final obliteration of the lumen of the appendix.

This paper was not discussed.

DR. L. M. TIFFANY, of Baltimore, read a paper on

THE TECHNIQUE OF CRANIAL SURGERY.

He dwelt at some length on the difference between traumatic and pathologic operations, the best way of gaining access to the brain, and the various methods of arresting hemorrhage.

He also went into considerable detail concerning the recognition of the brain area presenting through an opening in the skull, the removal of intracranial structures, and the closure of the wound.

DR. W. W. KEEN, recommended Pyle's chisels for

opening the skull, and stated that no rule could be laid down as to the size of the opening necessary, each case being a law to itself. He was not in favor of the employment of the dental engine in opening the skull for several reasons, but he was in favor of osteo-plastic operations in certain cases. He advised that the operation should be performed in two stages. The interval between each to be governed according to the special case.

DR. WEIR, of New York, discussed the question of hemorrhage and the various methods of controlling it. He has to a large extent given up the use of the chisel, and rarely resorts to osteo-plastic operations.

DR. J. PARMENTER, of Buffalo, preferred the gouge and hammer to the chisel, as he considers them less dangerous. He advised against the practice of palpating the intracranial structures, and laid great stress upon the importance of cleanliness in these operations.

DR. S. J. MIXTER, of Boston, considered that no trephine should be over three-quarters of an inch in diameter, and believed in the employment of extensive flaps rather than running the risk of having to enlarge the incision. He also suggested the placing of a piece of celluloid between the skull and the skin to prevent adhesion where the operation is performed in two stages. He thought the questions of how much pressure the brain could stand, and how much compression was safe in the case of hernia of the brain were very important. He recommended the presence of a skilled pathologist when exploring the brain, so that removed fragments might be immediately examined and their true nature determined.

DR. CHRISTIAN FENGER, of Chicago, read a paper entitled

URETERECTOMY.

He stated that ureterectomy has been performed for tuberculosis, suppuration in the dilated ureter, hydro-ureter and non-infected dilated ureter. He referred to the operations as primary, secondary, total and partial. He considered a primary as one when the ureter is removed simultaneously with the kidney; a secondary operation when, after nephrectomy, the removal of the ureter of the same side becomes necessary; as total when the entire ureter is removed; and as partial when only a portion of the ureter is removed. He gave four methods of operating: trans-peritoneal, extra-peritoneal, sacral and trans-vaginal.

DR. A. T. CABOT, of Boston, saw no especial advantage in transplanting the end of the ureter into the vagina, and he thought the discharge from the lumbar fistula quite as endurable as from the vagina. He advised that the ureter should be cut off as low as possible when it was tuberculous, stating that the remainder could be removed, if necessary, subsequently.

DR. M. H. RICHARDSON, of Boston, showed some colored illustrations from a case of extirpated ureter.

Dr. Richardson also read a paper entitled,

A CASE OF FENGER'S PYLOROPLASTY FOR INTERMITTENT HYDRONEPHROSIS.

In this case it was only when pain and tenderness were present that the tumor could be felt, and it was supposed to be a distended gall-bladder, but proved to be an enlarged renal pelvis. After describing at some length the steps of the operation, the author

stated that the patient made a good recovery and has no recurrence of the symptoms.

Dr. Richardson then presented another paper entitled

A CASE OF CHRONIC INTESTINAL OBSTRUCTION FROM INCOMPLETE VOLVULUS OF THE SIGMOID FLEXURE.

The case occurred in a man, forty-seven years of age, who had constipation alternating with watery discharges, and occasionally sudden pains. Upon opening the abdomen, the sigmoid flexure was found to have a capacity of at least two gallons, and was so twisted upon the colon as to obstruct the fecal flow. After untwisting the colon it was fastened to the abdominal wall, and the patient made a complete recovery.

DRS. H. L. BURRELL, and R. W. LOVETT, of Boston, read a paper on

HABITUAL DISLOCATION OF THE SHOULDER-JOINT.

The authors mentioned several methods of treating these cases, referred to the way in which the x-ray and the fluorscope acted in such cases, and also to two cases successfully operated upon.

Many other papers were read by title, after which the Society went into executive session and elected the following officers: President, Dr. T. F. Prewitt, St. Louis, Mo.; Vice-Presidents, Dr. J. McFadden Gaston, Atlanta, Ga., Dr. M. H. Richardson, Boston; Secretary, Dr. H. L. Burrell, Boston; Treasurer, Dr. G. R. Fowler, Brooklyn.

The next meeting of the Association will occur at New Orleans, April 20, 1898.

Recent Literature.

A Practical Treatise on Medical Diagnosis. For the Use of Students and Practitioners. By JOHN H. MUSSER, M.D., Assistant Professor of Clinical Medicine, University of Pennsylvania, Philadelphia. New second edition, thoroughly revised. In one octavo volume of 925 pages, with 177 engravings and 11 full-page colored plates. Philadelphia and New York: Lea Brothers & Co. 1896.

The second edition of Dr. Musser's *Diagnosis* follows the first at an interval of two and a half years. This in itself is a tribute to the recognition of its qualities. The author has availed himself of the opportunity to enlarge the text by between fifty and sixty pages, the book has been thoroughly revised, the results of recent investigations have been incorporated, and additions have been made to the illustrations. The book is therefore well up to date. In truth, activity in medical research and in the sciences bearing on medicine is so great at the present time, that revision of a book used by students as a text-book and by practitioners for reference in their daily work is practically necessary at least every three or four years.

In regard to the plan and execution of Dr. Musser's book, we have only to repeat what was said of the first edition. The volume is still of a manageable and convenient size, the presentation by the publishers — paper, type and illustrations — leaves little if anything to be desired.

Diseases of the Stomach. A Text-book for Practitioners and Students. By MAX EINHORN, M.D., Instructor in Clinical Medicine at the New York Post-Graduate Medical School and Hospital; Visiting Physician to the German Dispensary. 496 pp. New York: William Wood & Co. 1896.

Dr. Einhorn's book is dedicated to Professor Ewald, of Berlin, as friend and teacher. This suggests the scope of the book, and reminds the reader of the attention given during the last twenty years, to the investigation of the physiology and pathology of the stomach and of the more accurate knowledge of the functions and disorders of that viscus which has been gradually developed during that time. "Dyspepsia" is no longer a sufficient diagnosis for either physician or patient. A point has even been reached where there is great danger that the diagnosis and treatment of diseases of the stomach may become a "specialty." New processes for physical examination have been devised, and chemical tests applied to the gastric secretions. The technique is not for all of these absolutely simple, and the apparatus has grown to be numerous as well as ingenious. It is the exceptional practitioner who is possessed of a gastrodiphane or is prepared to give his patient the benefit of transillumination of the stomach.

This volume has 478 pages, and its contents are divided into fourteen chapters: the first four treat of anatomy and physiology, methods of examination, diet, local treatment of the stomach; the next four chapters are devoted to organic diseases with constant lesion; the next three to functional diseases with variable lesions; Chapter XII deals with abnormal conditions with reference to the size, shape and position of the stomach; Chapter XIII elucidates at considerable length, as due to its importance, the nervous affections of the stomach; and Chapter XIV is given to the condition of the stomach in diseases of other organs.

The author has produced in the English language a useful book of practical value to the practitioner on an important subject — a subject which he had previously discussed in the eighth volume of the "Twentieth Century of Practice."

A Manual of the Practice of Medicine. Prepared especially for Students. By A. A. STEVENS, A.M., M.D., Lecturer on Terminology and Instructor in Physical Diagnosis in the University of Pennsylvania. Fourth edition, revised and enlarged. Illustrated. Philadelphia: W. B. Saunders. 1896.

The fourth edition of this excellent manual contains important modifications and additions. A number of articles have been rewritten in conformity with modern progress in our knowledge of the subjects of which they treat, and a short appendix giving an exceedingly brief account of the examination of the blood and of the gastric contents has been added. To the study of the white blood-corpuscles only a page and a half is given, including a large cut, a brevity which seems extreme even in a manual.

The book, as a whole, contains a vast amount of knowledge condensed into a very small space, and resembles in many of its descriptions a medical dictionary. It will be a useful reference book for students and may also serve as an outline of a course of study on this subject.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, MAY 27, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE SURGICAL TREATMENT OF ACUTE PERITONITIS.

DURING the past twenty years, great interest has attached itself to the surgical treatment of all forms of peritonitis, and especially of the tubercular form.

Sir Spencer Wells operated in a case of the latter kind as far back as 1862 and effected a cure. Ceccherelli, several years subsequently, reported 88 cases, three of which only were his own; 55 of these cases resulted in permanent cure. Trzebicky, in 1888, collected the particulars of 54 cases, of which 40 were cured; and Kümmell out of 40 cases reported 35 recoveries. The objective signs were generally those of an encapsulated ascites.

Lawson Tait, in 1888, reported a case of puerperal peritonitis in which he performed laparotomy with a successful result. Acute peritonitis appeared on the third day, after a severe labor, and soon became general. On the fifth day there was great distention, pulse 135, hiccough and excessive vomiting. The day following, the condition of the patient was worse. Laparotomy was performed, and a bloody, purulent fluid was evacuated after separating the adhesions; the uterus was adherent to the pelvis on the right side. A glass drainage-tube was passed deep into the pelvis, and the wound was closed. The unfavorable symptoms disappeared promptly, and the patient recovered.¹ Tait subsequently reported eight cases of acute peritonitis treated by laparotomy and drainage after thorough cleansing of the abdominal cavity. Six of these made a good recovery.²

Since then cases have multiplied in foreign lands and in this country, and all our leading surgeons have had a more or less favorable experience in laparotomies for peritoneal inflammations. According to Wylie, Gordon, Davis, Price, Mears, Cushing and others whom we might name who have written on the subject, abdominal section is imperatively demanded when-

ever the peritonitis becomes general and signs of pus are manifest. It is the only thing that gives a chance of recovery. Drainage should be employed in all cases.

It is easier to understand the beneficial effects of laparotomy, irrigation and drainage in acute septic cases following abortion, appendicitis, perforation of the stomach or duodenum by an ulcer, etc., than in tuberculous peritonitis, where the operation certainly seems often to do good. Fehling attributes the results to the change of pressure in the abdomen and the contact of extraneous germs with the bacillus tuberculosis.³ Lauenstein believes that the withdrawal of the ascitic fluid is an important factor, as the tubercle-bacilli cannot thrive on the dry peritoneum. He also thinks that exposure to sunlight during the operation has a curative influence.⁴ Osler thinks that cases with fresh eruption and considerable effusion, whether free or sacculated, offer the best chance of recovery, as the tubercular disease is more likely to be primary in the peritoneum, the general condition is usually better, and the subsequent chances of general infection are much slighter.⁵ In cases, then, with somewhat sudden onset, rapid development of ascites, with flow of moderate grade, we may be most sanguine of success.

The treatment of diffuse septic peritonitis, however, from the acuteness and severity of its symptoms, and the frightful rapidity of its progress toward a fatal termination, without, and often in spite of, surgical treatment, presents problems of tremendous interest and importance to surgeons who are called, too often unfortunately as a last resort, to attempt to save the life of the unfortunate victims of this disease. Recovery from an acute septic process diffused throughout the enormous cavity of the peritoneum, with its tremendous absorbing surface, is, of course, out of the question without the freest possible drainage and most thorough cleansing. But, in addition to cleansing and drainage, which must be secured with the least possible damage to the inflamed and roughened serous surface, the weakened and parietic muscles of the intestine must be stimulated to peristaltic action, or the bowels will not move, and the distention, fecal vomiting, etc., will continue till the fatal termination. All these objects must be accomplished in patients whose nervous system is intoxicated by the absorption of the septic products of bacterial growth, and whose strength is thereby reduced almost to the lowest ebb. Surely a difficult problem for the surgeon to grapple with. The prognosis of the disease, if untreated, is, however, so bad, that the attainment of success, even in a small proportion of cases, is a worthy reward for the surgeon's efforts.

The subject in all its bearings was recently discussed at the Twenty-sixth Congress of the German Society of Surgery held in Berlin, April 21-24, 1897.

Körte spoke of acute purulent peritonitis from lesions of the stomach, intestines or uterus. He has

⁴ Centralblatt für Chirurgie, Leipzig, No. 42, 1890.

⁵ Johns Hopkins Hospital Reports, 1890.

observed 99 cases during the last seven years. In 71 cases laparotomy was performed, with 25 recoveries (the cases were all bad cases). He first taps the abdomen to remove exudate (if there be any), then makes a free incision in the middle line. He regards the washing out of the peritoneal cavity as a matter of indifference; when done, only boiled water should be used. He cautions against much manipulation of the intestines. The establishment of good drainage is essential. He cautions against opium in the after-treatment. If there is much vomiting, he would perform lavage of the stomach. The bowels should be kept open. Of the 71 cases operated on by him, 34 were the result of appendicitis; 13 recoveries. In six cases the peritonitis was due to perforation of the stomach or duodenum; only one cure. In 31 cases the peritonitis proceeded from suppurative disease of the uterus and tubes; of these there were only six recoveries. The prognosis of peripheral peritonitis is better than that of central peritonitis, because the former presents a smaller surface for absorption than peritonitis localized in the coils of the small intestine.

König, of Berlin, stated that he had recently operated for two cases of perityphlitis presenting the symptoms of general peritonitis. In the course of the operation, he came upon numerous circumscribed abscesses; there was no diffused exudation. Such cases are sometimes, though incorrectly, classed as diffuse peritonitis. In operating, he never washes out the abdominal cavity; he makes a very free opening into the abdomen. He would urge the importance of extending the same surgical treatment to puerperal peritonitis, and to suppurative peritonitis from whatever cause, considering the very bad prognosis of these affections when left to themselves. A laparotomy is never to be undertaken unless there is a fair pulse and the patient is in a good condition to rally after the operation.

Sonnenberg, of Berlin, said that he was in the habit of making the incision in the right hypogastric region, seeing that most of these peritonites are of perityphlitic origin. This incision leads directly to the primitive focus of the suppuration, and exposes the surgeon much less to the risk of tearing the adhesions which may exist between the abscess and the abdominal cavity than when the opening is made in the linea alba. He opens the abdominal cavity freely and packs with antiseptic gauze for drainage.

Israel, of Berlin, also believes in the free abdominal opening, and in desperate cases makes a large crucial incision of the abdominal walls; he then packs in iodoform gauze. He claimed more successful results since he had adopted this method.

The discussion of the same subject before the recent Congress of American Physicians and Surgeons in Washington brought out some interesting differences of opinion as to operative methods. The speakers were naturally in accord that free irrigation with normal salt solution and drainage were essential to success; but the advocacy of Dr. McCosh of the pro-

cedure of drawing the coils of small intestine outside the abdomen for more thorough washing, met with considerable opposition. It must certainly prolong the operation, a matter of serious moment in this class of cases, and there is certainly a possibility of increasing the shock.

A very thorough washing can be done through a large tube passed to the bottom of the deep recesses of the abdominal cavity without drawing out the intestine.

The injection of saturated solution of magnesium sulphate into the small intestine through an aspirating needle, which has been done by Dr. McCosh, is a procedure which seems worthy of trial. Dr. McCosh's record of success in six out of eight cases operated upon is certainly an excellent one.

Drainage by gauze wicks arranged as siphons, and of tubes (preferably glass), passed to the bottom of the pelvis are of the greatest importance.

Although the success which Dr. McCosh has achieved has so far failed to crown the efforts of most surgeons who are called upon to treat these cases, there is reason to hope that the development of a thorough and at the same time rapid technique, and the adoption of every means which can be employed to encourage peristalsis, may be sometimes successful in saving a life. Many points in the methods of draining the peritoneum remain yet to be perfected, and afford a field for the surgeon's inventive efforts.

MEDICAL NOTES.

THE LATEST ASSOCIATION.—Now comes the American Gastro-Enterological Association.

THE MISSOURI STATE MEDICAL ASSOCIATION.—This Association held its fortieth annual meeting at St. Louis, May 18, 19 and 20, 1897.

PLAGUE IN BOMBAY.—Plague in Bombay is declining. For the week ending May 7th, there were 130 deaths. In the Cutch district, north of Bombay, plague continues with marked severity.

INSPECTION OF SCHOOLS IN BALTIMORE.—The Health Department of Baltimore has begun the systematic examination of the throats of school children where diphtheria is suspected.

DR. LUCY WAITE, the wife of Dr. Byron Robinson, has been elected head physician and surgeon to the Mary Thompson Hospital, of Chicago. The hospital is devoted to the diseases of women and children; it has a capacity of eighty beds.

DR. JOHN B. HAMILTON.—Dr. John B. Hamilton, formerly of the Marine-Hospital Service under Surgeon-General Wyman, has gone to the Illinois Northern Hospital for the Insane, at Elgin, to assume the duties of Superintendent. We understand that, while abandoning his extensive surgical practice in Chicago, he will still be retained as editor of the *Journal of the American Medical Association*.—*Medical Record*.

A TESTIMONIAL TO HENRI DUNANT. — A committee has been formed at Stuttgart for the collection of funds for a testimonial to M. Henri Dunant, the founder of the Red Cross Association, and promoter of the Geneva Convention.

A MEDICAL SENATOR. — After a protracted struggle in the Kentucky Legislature, that body, on its sixtieth ballot, elected Dr. Wm. J. Deboe as United States Senator. During the sessions Dr. Wm. G. Hunter led in the race, but always lacked from one to five votes. Both of these gentlemen are well-known and reputable physicians. Dr. Hunter is now a member of the National House of Representatives. All honor to these gentlemen, and all honor to their constituents! Drs. Hunter and Deboe are all the more useful to their State and to the nation by reason of their medical education. — *Cincinnati Lancet-Clinic*.

BOSTON.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, May 26, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 64, scarlet fever 80, typhoid fever 6, small-pox 1.

NEW YORK.

A PRACTICAL TEST OF THE BERTILLON SYSTEM. — The first practical test of the Bertillon system of identification in the criminal courts of New York has just been made in the Court of General Sessions in the case of a thief giving the name of Reynolds, who in February last was detected in the act of entering the second story of a residence. He broke his leg in jumping to the ground, and was easily captured. The chief of the detective force sent his photograph and description to the heads of police of all the leading cities, with the result that he was identified by the Chief of Chicago as John Coogan, who had served a term in Joliet prison, and by the Chief of Philadelphia as John Martin, who had been convicted of burglary there. At his trial the man strenuously denied his identity with either Coogan or Martin, but the evidence presented by the identification cards sent from Chicago and Philadelphia was so conclusive that both the judge and jury were thoroughly convinced that he was an old offender.

THE NEW YORK PUBLIC LIBRARY. — The bill providing for the construction of the New York Public Library, Astor, Lenox and Tilden foundations on the site of the reservoir at Fifth Avenue and 42d Street, and appropriating \$2,500,000 for the purpose, which recently passed the legislature, has been signed by the governor, and the work of removing the reservoir will be commenced at once. Dr. John S. Billings, director of the library, has lately visited a number of the principal cities for the purpose of inspecting their libraries, and, in company with the Professor of Architecture of Columbia University and the constructing engineer of the Library of Congress, will

select the six most satisfactory plans for the building submitted in competition by architects. The final selection of the plan from these six will be made by a committee of seven experts. A feature of the new library will be a department for the blind.

DEATH OF DR. JOHN P. ATWATER. — Dr. John P. Atwater, last surviving member of the class of 1834 at Yale College, died at his home in Poughkeepsie on May 23d. He was born in 1813 at Carlyle, Pa., where his father, the Rev. Jeremiah Atwater, was President of Dickinson College. Dr. Atwater, after completing his professional studies, settled, in 1837, in Cincinnati, where he was very successful and accumulated a fortune by investments in business property in Chicago. In 1870 he removed to Poughkeepsie.

Miscellany.

THE AMERICAN MEDICAL ASSOCIATION.

THERE is soon to be held in Philadelphia the annual meeting of the American Medical Association, at which will be celebrated the completion of the first half-century of its existence. Great preparations are being made by the physicians of Philadelphia to realize the expectation that this will be the most successful meeting the association has ever had, and we sincerely trust the result of these labors will fully meet the highest anticipations of Dr. Hare and his efficient co-workers on the committee of arrangements.

There are apparently but two dangers ahead, and we trust these can be avoided by skilful management. The first of them is the enormous list of papers with the reading of which the various sections are threatened — seventy-six papers in the section on laryngology and otology, ninety-three in the section on general medicine, and others in proportion. Of course many of these are merely announced as to be read, the authors never meaning to read them, even if they ever write them, but with these aside there will be enough left to occupy every minute of the four sessions of each section, to weary every suffering member of the section, and effectually to strangle all discussion. No good to anybody can come from the hurried reading of paper after paper, shutting off the long-winded speakers in the middle of their argument, and so limiting discussion as to make it barren of any result. This is a danger to which the association is exposed in its scientific character. But what most menaces its usefulness, and will always, as long as it lasts, prevent the American Medical Association from attaining the position it should occupy as the representative body of the American medical profession, is the everlasting quarrelling which disturbs the general meetings and disgusts all who think the grabbing of offices is not the chief end of medical man. Of late years the great bone of contention has been the secretaryship of the association. The present most capable secretary, Dr. Atkinson, has performed the arduous duties of his office in a most efficient manner for many years, and a meeting without his genial presence might, indeed, be a medical meeting of some sort, but it would hardly seem like one of the American Medical Association. Even the father of the association himself would

scarcely be more missed. Yet for years this faithful servant of the association has been compelled to sit upon the platform and listen to accusations of incompetency and worse brought against him by young men who were unheard of and undreamed of when he first took up the cares of the office which he fills with so much honor to the society. The fact that the constitution of the association makes the office of secretary a permanent one has hitherto stood in the way of Dr. Atkinson's enemies; but at this coming meeting, held in the City of Brotherly Love, the home of the secretary and the birthplace of the association, these men hope to carry through an amendment to the constitution whereby they will be enabled, if they can pack the meeting efficiently, to depose the secretary and elect another man to serve in his place. We hope for the good of the association and for the honor of American physicians that their plans may be thwarted. — *Medical Record.*

Obituary.

BENJAMIN EDDY COTTING, M.D.

DR. BENJAMIN EDDY COTTING died at his home in Roxbury on May 22d, aged eighty-four years. He was born in Arlington, Mass., on November 2, 1812, was graduated at Harvard in 1834, and at the Harvard Medical School in 1837. He began the practice of medicine on Washington Street, Boston, and later moved to Winter Street.

In 1841-2 he assisted Dr. Jeffries Wyman as curator of the Lowell Institute; and in 1843, on Dr. Wyman's resignation, he became curator, a position which he held with honor and credit for fifty-five years, or until March of the present year, when owing to his increasing infirmities he resigned.

In 1843 Dr. Cotting moved to Roxbury, where he built up an extensive practice, in which he was actively engaged up to the last years of his life.

In 1872-74 he was vice-president of the Massachusetts Medical Society, and from 1874-76 its president. For many years he was a consulting physician to the Boston City Hospital.

He was very influential in reorganizing the JOURNAL at one time, and in placing it under a board of management of which he continued to be a member.

We hope in another issue to present a more critical appreciation of Dr. Cotting's life and influence upon his contemporaries.

GEORGE W. BURDETT, M.D.

DR. GEORGE W. BURDETT, of Clinton, Mass., whose death was noted in our issue of May 13th, was for many years a physician of prominence in Worcester County.

He was born in Clinton in 1819, and studied at the Dartmouth and Harvard Medical Schools, graduating at the latter in 1846. He began practice in Clintonville immediately after graduation.

He became a trustee of the Clinton Savings Bank on its organization, and was the last one of the original board. He had been the first vice-president since 1885. During the first three years after the incorporation of the town he served on the school committee and helped organize the new school system. He was for many years a member of the board of directors for the Bigelow Free Public Library. He was the chief agent in the organization of the Baptist Church of Clinton and served as its clerk for forty years or more.

He was married and had seven children, five of whom are living.

Correspondence.

PUBLIC HEALTH IN VIENNA.

VIENNA, April, 1897.

MR. EDITOR:—In Vienna, one of the great capitals of Europe, and the Mecca of medical students for many years, one would naturally expect to find the most modern and the most scientific methods of health work. Such however, is not the case. The Viennese are scientific and able; therefore, theoretically, their work is good. Unfortunately, the usual Austrian indolence characterizes the practice.

The central health office, or *Stadtphysikate*, is situated in the *Rathhaus*, and is under the direction of Herr Physikus Löffler. There are, besides, various sub-offices, and a physician and inspector for each of the nineteen districts of the city. These local physicians attend to the health work in their several districts, but make full reports to the central office.

Each practising physician in the city receives from the health office a number of printed blanks. These blanks are so arranged that they may be divided into two parts. The upper part has spaces for the name of the patient, residence, disease, date of disease, etc. On this part of the blank are also instructions to the physician as to isolation of the patient, disinfection of the sick room, burning of waste stuffs, disinfection of instruments, as also of the dejections in typhoid, cholera, dysentery, diphtheria and scarlet fever, and the sputum of tuberculosis, diphtheria and pneumonia. Instructions are likewise given as to the care that must be taken by the attendant, the disinfection of the attendant, and the exclusion of strangers. When a physician meets a case of infectious disease, he fills out this upper part of the blank, tears it away from the lower, and sends it to the health office. The Imperial post carries all such papers free.

The local health physician is immediately notified of the reception of the paper. He visits the house, and fills out another blank, which contains the number of children in the house, the number attending school, which schools they attend, the isolation, the manner in which the instructions as to disinfection are carried out, and any other necessary details. This is also forwarded to the central office, and inspected by Herr Physikus Löffler, who may either approve or order another inspection as he chooses. The attending physician must make his own bacteriological examinations, as no facilities are offered him by the government.

When illness is ended, the practitioner fills out and sends in the lower part of his blank, on which he writes the name and residence of the patient, the date of recovery or death, date of removal to hospital, or of any other removal, to what place, and in cases of diphtheria he states whether or not he used serum. On the verification of this report, the house is disinfected. The trouble with the system is, that too much responsibility is placed on the shoulders of the family physician. We need waste no pity on him, however, for if he be a true Austrian, he will quickly shift the weight on to some one else.

There are six sub-stations of the health department, one for every three districts of the city. Each of these stations contains a small steam-sterilizer, an oven for burning straw mattresses and other worthless objects, and all the various smaller articles necessary for disinfection. Three of them (one for each six districts) contain besides, ambulances for the removal of the sick, and a wagon for the transportation of the bodies of those who have died of an infectious disease. There are four ambulances in each of the three larger stations, two for infectious diseases, and two for non-infectious and accidents. The health department is responsible for all transportation to the general hospital.

A pamphlet is issued from the central office, giving explicit directions, first as to the general disinfection, then as to the particular care to be taken after each of the various infectious diseases. All objects which are easily movable must be taken to one of the stations, and there rendered

sterile, preferably by steam. It is especially enjoined that no article shall be removed from an infected room, unless it is thoroughly wrapped in sterilized cloth. For general disinfection in the apartment it is recommended that five-per-cent. carbolic acid, or two-per-cent. lysol solution be used for all washable objects, ordinary floors, walls, and unpolished furniture; two-per-cent. carbolic or one-per-cent. lysol for polished furniture, pictures, books, waxed floors and ornaments; and slaked lime for water closets, cesspools, sinks, and unclean water-courses of all kinds.

The carbolic and lysol solutions are applied by means of a hand-pump, either in the form of spray or solid stream, according to circumstances. Soft soap is also plentifully used, and the rooms are finally freely opened to the air. Attendants of the sick must not only bathe in disinfecting fluids, but must also thoroughly wash out the hair of the head and beard in a strong soft-soap solution.

The articles to be removed are placed in a small, tightly-closing, zinc-lined wagon, and taken to the nearest sub-station. There they are treated by steam if possible. A maximum thermometer (registering 100° C.) is placed in the centre of the articles to be disinfected, and they are then put into the sterilizer. There is another thermometer on the outside of the apparatus which registers the heat of the interior. When this thermometer shows a temperature of 100° C, the time is noted. The heat is kept up for an hour. After that, one half-hour is given for ventilation. The goods are then removed from the other side of the boiler, in the usual way. It is fairly easy to disinfect thoroughly by means of these sterilizers, because each apparatus is so small, that but a limited quantity of goods can be treated at once. Therefore the heat quickly reaches the centre. They are economical, also, as the fires need not be constantly kept up. A sharp wood fire will quickly generate steam enough for all purposes.

The defect lies in the placing of a steam apparatus here and there, in different parts of the city. Steam sterilization inefficiently performed, is worse than useless, and in the scattering of the responsibility we necessarily multiply the chances of carelessness. This might be remedied, however, by the use of an automatic register for each operation, as is done in Rome.

Furs, feathers, leather articles and such things as cannot be treated by steam, are subjected to formaldehyde gas. There is in each station, a simply made, air-tight chest, having shelves around its sides, the centre being open from top to bottom. The infected objects are ranged along the shelves, a solution of formalin is poured over blotting paper previously placed on the bottom of the chest, and the lid if closed down and fastened. The lid comes down a little way over the sides of the chest, and is provided on all its edges, with strips of felting somewhat resembling our weather strips for doors and windows. The gas arising, is thus enabled to penetrate everywhere through the chest, but cannot escape. After twenty-four hours, the box is opened, and the goods removed.

You are all probably aware by this time, of the experiments in disinfection by formaldehyde made in Venice during the recent Sanitary Congress. These experiments were made according to the method for disinfection of ships, advocated by Dr. H. D. Geddings, of the U. S. Navy, and Dr. J. J. Kinyoun, of the U. S. Marine-Hospital Service. Various test-tubes containing cultures of bacilli of cholera, diphtheria, etc., were placed, opened, in two rooms with an open connecting door. Other objects were then scattered about the rooms, after which the windows and doors were sealed by strips of paper. Formaldehyde was introduced into one of the rooms by a small metallic tube passed through the keyhole. This tube led from the top of a metallic cylinder, which contained about two litres of formaldehyde, and the steam was generated by a small alcohol lamp underneath. The steam was kept up for twenty-five minutes, and the rooms remained closed for three hours afterward. Inoculations from the cultures in the tubes, were made on animals with negative effect. Not only that, but it is said that the walls of the rooms remained sterile for three days. Moreover, none of the various arti-

cles left in the rooms, such as furs, fabrics, etc., were at all injured. Dr. Sédan, who conducted the experiment, is said to have been thoroughly convinced of the practicability of using formaldehyde gas as a disinfectant of houses after infectious diseases. I asked one of the health-department men in Vienna, as to his opinion, and he said that he thought there was no question about the efficacy of the gas for the purpose, but that it was too expensive to be used in such a wholesale manner. I do not believe, however, that it would be suitable for general use in American cities. A gas, to be a good disinfectant, must be exceedingly volatile. It must seek out, and creep through all interstices. Such a gas may be easily lost before it has performed its office.

Dojardin-Beaumetz, formerly one of the strongest advocates of sulphur disinfection, was once commissioned by the French Government to disinfect barracks, which had been used by the troops during an outbreak of cholera. He found sulphur practically useless for the purpose, on account of the loose construction of the buildings, and the consequent escape of the gas. Again, a light, volatile gas constantly arises, and it must needs be very perfectly confined, and for a long time, under strong pressure, before it would exert much influence on the floor and lower walls of a room, which are the parts most contaminated during an illness.

Any one, who has remained for any length of time in one of our draughty tenement-house rooms, with its shrunken door, its rattling easements, its cooking-stove with innumerable openings, its large chimney and imperfectly fitting fire-board, will easily understand how difficult it would be to make such an apartment air-tight, therefore, and how hazardous would be our dependence on a gas like formaldehyde. Used as it is in Vienna, in an especially made air-tight receptacle, I believe that formaldehyde is a valuable agent, and a powerful adjuvant in health work, but I should hesitate to rely very strongly upon it for general house disinfection.

As to the directions given for each particular infectious disease, in the pamphlet which I have mentioned, Asiatic cholera naturally takes the first place. Then comes variola and diphtheria. It is then enjoined that tuberculosis be handled with the same care that is given to diphtheria. Of course, the same isolation cannot be maintained, but the attendant must exercise the same precautions in regard to clothing, drinking-vessels, etc., and the room must be as thoroughly disinfected after death or removal. After instructions are given for scarlatina and typhoid, there come a number of diseases of which we take little notice, such as varicella, puerperal fever, mumps, dysentery and influenza.

The law in regard to vaccination is the same as with us, that is, that an unvaccinated child cannot enter the public school. The scarred faces that one sees in the clinics and hospital wards amply testify to the inefficiency of the law and the laxity of its observance.

There are absolutely no plumbing regulations in Vienna. I have as yet failed to find, outside of the hotels, a properly trapped sink, and the water-closets are enough to make a pious sanitarian swear. There are very few automatically flushed closets. They are nearly all of the old-fashioned pan variety, and are provided with a tiny tank, inserted with devilish ingenuity between the occupant's back and the wall. These tanks are not connected with running water, but are filled, once in a while, by the housewife or servant with water carried in from the kitchen sink. A very filthy closet frequently results.

Stable laws are also conspicuous by their absence. One hires apartments in a very good quarter of the city, and a week after, along comes a gentleman who engages the ground-floor, and stables three or four horses under one's courtyard windows. There is absolutely no redress, since this is the custom of the city.

Although the public baths are not under the control of the health department they still belong to the public health and merit a short description. In the summer are the swimming baths on the Danube, with which we have noth-

ing to do, as our facilities for such things are much better at home. In the winter are opened in different quarters of the city, eleven *volksbaden*, or baths for the general public. These are all of the same general character, and include places for both men and women. Admission is to be gained on payment of five kreuzers (2½ cents). This entitles one to the use of a locked cupboard for the clothes, to a bath, and two towels, one to be tied about the loins, and the other for drying purposes. Soap is furnished at one kreuzer more, or the bather may furnish his own soap. Although both men's and women's baths may be contained in the same building, the entrances are entirely distinct. A description of one of the men's baths will suffice for all.

One enters first a central corridor from which open doors to the right and left respectively. The door on the right leads into the men's dressing-room, that on the left into the boy's apartment. Both of these dressing-rooms open into the same bathing-room, which runs at right angles to them. The dressing-rooms and bathing-room form three sides of a rectangle. Although the two dressing-rooms open into either end of the same apartment, still the men and boys do not come into contact while bathing, as a partition about eight feet high separates one part of the room from the other. The same division exists between the women and girls. The locked cupboards for clothing resemble somewhat those in our own gymnasias, but are higher and narrower.

The bathing-room has no tubs, but is divided by iron or zinc partitions into small open compartments, each containing a shower bath. The brick flooring is covered with strips of manilla matting, and each bathing-compartment has a small, low, wooden platform made of slats about one-fourth of an inch apart. The bathers' feet are thus kept warm and comfortable.

It would seem to me that bathing-places such as these would answer well our requirements in Boston during the winter months. We need no swimming tanks as we have ample facilities for sea bathing in summer. Tubs in such an establishment would mean a waste of space, time and money. One tub would require the space of two or three showers, and four or five men could use a shower, while a tub was being filled, used, emptied and cleaned. Whatever would waste space and time, would waste money since extra rentals and extra salaries of attendants would be required for the same amount of work performed.

On no account, however, should such baths be placed in, or about the premises of our public schools. They are sufficiently overcrowded already, and it is sufficiently difficult to provide proper light and ventilation without further complicating the problem. Besides, we have among our present foreign population many semi-civilized men from tropical climes; men who are children of nature, who have frequently untrained minds, and, perhaps, unbridled passions. It would be better for our children that such men should not be taught to loiter in the vicinity of our schoolhouses. It would be exceedingly easy to rent the basement floors of business buildings in the various districts of our city, and fit them for the purpose. Such bathing-places would be efficient and economical.

I am tempted here to introduce a somewhat irrelevant, but exceedingly important matter, and that is a consideration of the dressing-rooms in our public schools. It has seemed to me for some time that the cases of infectious disease contracted in our public schools were not so likely to be from actual contact of the scholars in the school-room, as from the clothing in the dressing-rooms. Our school dressing-rooms are exceedingly small, and the hooks, generally in two rows, are exceedingly close together. The children's wraps are piled closely, one on top of the other. The wraps are frequently damp, either from the playing in the snow or the thousand and one other careless things that school-children are apt to do. This damp clothing is placed in a warm, steam-heated room, and is thus subject to conditions most favorable to bacteriological growth. One can easily see how a child coming from an infected house might spread disease. In fact, these rooms are very pretty incubators for bugs, both macroscopic and microscopic.

While I am not going to advocate a locked cupboard for each youngster's coat, I still think that a remedy exists. In the first place all dressing-rooms, already existing, might have a thin partition between the hooks so that there would be no actual contact. Secondly, that walls and floors might be altered so that such rooms could be drenched with corrosive or some other disinfectant solution at least once a week, and in times of danger every day. Every new school-house should have ample dressing-rooms with partitions, and should be constructed like a ward in a contagious-disease hospital, so that proper disinfection could be done at all times, or better still, all the clothing could be hung in different sections of a locked basement which could be so built that it might be hosed down at any time, or possibly could be closed up so that a full head of steam could be turned in. With such appliances, I am satisfied, that many cases of contagious disease would be prevented, and many young lives saved. It is time to return to Vienna, although it does seem good to wander about Boston's schools for a while.

Many regulations of the health department of this city are imperative, because of the want of co-operation on the part of the local practising physicians. For instance, it is enjoined that if a child be presented for treatment at the polyclinic, and is found to have an infectious disease, it shall be sent by the physician of the clinic to a room provided for the purpose, and there held until the arrival of the ambulance, in which it may be transported either to its home or to the hospital. A very good rule, this, and intended to minimize the chances of infection in public conveyances. In practice, it works like this: The physician at the clinic orders the child into the designated room, then turns to his class, and grumbles because he is requested to perform work which properly belongs to health employees. The mother of the child, finding no supervision exercised, soon tires, takes her child by the hand, and starts out for the nearest omnibus or horse-car. The ambulance arrives, finds nobody and departs. The occurrence occasions no surprise, as the physician, who is to blame, is perhaps a professor of the University of Vienna, and a professor of the University of Vienna is a law unto himself.

I imagine that cases which come under the ban of the department are frequently not reported, and since no opportunities are given for bacteriological examinations that many are never verified. Moreover, there are no forcible removals, and therefore, there is no penalty for the disregard of instructions as to isolation and disinfection during an illness.

Taking it all in all, the practical work in Vienna hardly paid me for the time stolen from my dermatological studies. Their regulations are good, however, and they should get credit for what they preach, even though their practice be imperfect. Yours very truly,

W. G. MACDONALD, M.D.,
Formerly City Physician of Boston.

A POSSIBLE EFFECT OF HIGH VOLTAGE ELECTRIC GENERATORS ON DISEASE GERMS.

BOSTON, May 10, 1897.

MR. EDITOR:—Since Röntgen's discovery I have been free from what is commonly called a cold. My profession exposes me constantly to contagion of this kind, for I operate at least every two or three days on the teeth of patients suffering from this disease. As I formerly suffered severely in this way, I attribute my present immunity to the fact that whenever I feel a cold beginning I start one of my generators and keep it running, taking the further precaution, when I have a few moments' time, to shut myself in a room with all the generators that happen to be in operative condition. As I feel quite sure there is some remedial action from these machines, I should like to see the air of hospitals charged in this way. Yours truly,

WILLIAM ROLLINS.

METEOROLOGICAL RECORD

For the week ending May 15th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 3,168; under five years of age 1,080; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping cough, erysipelas, diarrheal diseases and fever) 378, acute lung diseases 453, consumption 307, diphtheria and croup 156, diarrheal diseases 63, scarlet fever 59, cerebro-spinal meningitis 32, whooping-cough 27, measles 21, typhoid fever 21, erysipelas 10, small-pox 5, malarial fever 4.

From cerebro-spinal meningitis Boston 14, New York 8, Washington and Malden 3 each, Somerville 2, St. Louis and Worcester 1 each. From whooping-cough Philadelphia 8, New York 7, Chicago and St. Louis 3 each, Cleveland 1. From measles New York 10, Brooklyn 7, Chicago and Boston 2 each. From typhoid fever Philadelphia 12, St. Louis 3, Pittsburg and New Bedford 2 each, New York and Brooklyn 1 each. From erysipelas New York and Boston 3 each, Chicago, St. Louis, Baltimore and

Somerville 1 each. From small-pox St. Louis 2, New York, Chicago and Brooklyn 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,992,524, for the week ending May 8th, the death-rate was 17.0. Deaths reported 3,585; acute diseases of the respiratory organs (London) 232, measles 100, whooping-cough 96, diphtheria 43, diarrhea 36, fever 11.

The death rates ranged from 11.8 in Norwich to 30.4 in Preston; Birmingham 16.0, Bradford 14.0, Cardiff 12.0, Hull 15.8, Leeds 20.2, Leicester 12.8, Liverpool 19.9, London 15.5, Manchester 25.6, Newcastle-on-Tyne 14.6, Nottingham 18.6, Sheffield 19.1, Wolverhampton 19.1.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 15, 1897, TO MAY 21, 1897.

LIEUT.-COL. WILLIAM E. WATERS, deputy surgeon-general, will be relieved from duty at Columbus Barracks, O., on July 15, 1897, and will then proceed to his home, where, at his own request and for his own convenience, he is authorized to await retirement.

Leave of absence for one month, to take effect May 24, 1897, is granted MAJOR GEORGE W. ADAIR, surgeon, U. S. Army, Washington Barracks, D. C.

CAPTAIN CHARLES E. WOODRUFF, assistant surgeon, is relieved from duty at Fort Sheridan, Ill., to take effect June 1, 1897, and ordered to Fort Custer, Mon., for duty.

FIRST-LIEUT. POWELL C. FAUNTLEROY, assistant surgeon, is relieved from duty at Fort Niobrara, Neb., to take effect upon the arrival at that post of CAPTAIN PHILIP G. WALES, assistant surgeon, and ordered to Fort Robinson, Neb., for duty.

FIRST-LIEUT. CHARLES LYNCH, assistant surgeon, is relieved from duty at Fort Robinson, Neb., to take effect upon the arrival at that post of FIRST-LIEUT. FAUNTLEROY, and ordered to Fort Sheridan, Ill.

The leave of absence granted CAPTAIN EDWARD C. CARTER, assistant surgeon, is extended two months.

PROMOTIONS.

To be assistant surgeons, with rank of Captain, after five years' service. May 5, 1897.

FIRST-LIEUT. CHAMPE C. McCULLOCH, JR.

FIRST-LIEUT. FREDERICK P. KEYNOLDS.

FIRST-LIEUT. ISAAC P. WARE.

FIRST-LIEUT. ROBERT S. WOODSON.

FIRST-LIEUT. MADISON M. BREWER.

FIRST-LIEUT. GEORGE D. DE SHON.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE TWO WEEKS ENDING MAY 22, 1897.

J. C. WISE, medical inspector, detached from Marine Headquarters, Washington, May 15th, and ordered to Columbus, O., as delegate, Association of Military Surgeons. After duty at Columbus, ordered to the "Philadelphia," as fleet surgeon.

J. A. HAWKE, medical inspector, detached from the "Philadelphia," on relief, and granted three months' leave.

C. H. T. LOWNDES, passed assistant surgeon, ordered to duty at Marine Headquarters.

C. U. GRAYATT, surgeon, ordered to U. S. S. "San Francisco" (fleet), per steamer May 22d.

H. J. BABIN, medical inspector, detached from the "San Francisco," on relief, ordered home and granted three months' leave.

G. T. SMITH, passed assistant surgeon, ordered to the Naval Hospital, New York, temporarily May 15th.

M. S. ELLIOTT, assistant surgeon, detached from the "Columbia" and ordered to the "Indiana."

J. M. FLINT, medical inspector, ordered to examination for promotion, Washington, May 12th.

H. G. BEYER, surgeon, ordered to the Naval Museum of Hygiene for temporary duty in connection with the preparation of new microscopical outfits for ships and hospitals.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE WEEK ENDING MAY 15, 1897.

WHEELER, W. A., surgeon. Granted leave of absence for four days from May 17, 1897.

BANKS, C. E., surgeon. To inspect Service at New York, N. Y., Boston, Mass., Providence, R. I., New Bedford, Mass., Portland, Me., and Vineyard Haven, Mass. April 27, 1897.

CARRINGTON, P. M., passed assistant surgeon. Granted leave of absence for thirty days from May 26, 1897.

PETTUS, W. J., passed assistant surgeon. Granted leave of absence for seven days from May 11th, with permission to apply for extension. May 10, 1897.

STONER, J. B., passed assistant surgeon. To assume temporary command of Cape Charles Quarantine Station during absence of passed assistant surgeon W. J. PETTUS. May 10, 1897.

GARDNER, C. H., passed assistant surgeon. To proceed from Baltimore, Md., to Norfolk, Va., for temporary duty, upon completion of which to rejoin his station at Baltimore. May 10, 1897.

McMULLEN, JOHN, assistant surgeon. To report to medical officer in command of Service at Baltimore, Md., for duty. May 15, 1897.

APPOINTMENT.

JOHN McMULLEN, of Maryland, commissioned as assistant surgeon. May 12, 1897.

BRITISH MEDICAL ASSOCIATION.

The sixty-fifth annual meeting of this Association will be held at Montreal, on Tuesday, Wednesday, Thursday and Friday, August 31, September 1, 2 and 3, 1897.

The following are the officers of the Association: President, Henry Barnes, M.D., M.R.C.S., F.R.S.E., J.P., Physician, Cumberland Infirmary, Carlisle; President-Elect, T. G. Roddick, M.D., M.P., Professor of Surgery in McGill University, Montreal; President of the Council, Robert Saundby, M.D., F.R.C.P., Physician to the General Hospital, Birmingham, 83A Edmund Street, Birmingham; Treasurer, Charles Parsons, M.D., Dover.

Addresses will be delivered as follows:

MEDICINE. — Dr. W. Osler, F.R.C.P., Professor of Medicine in the Johns Hopkins University, Baltimore, U. S. A.

SURGERY. — Mr. William Mitchell Banks, F.R.C.S., Surgeon to the Liverpool Royal Infirmary.

PUBLIC MEDICINE. — Dr. Herman M. Biggs, New York.

The scientific business of the meeting will be conducted in eleven sections, as follows, namely:

MEDICINE. — President, Dr. Stephen Mackenzie, London.

SURGERY. — President, Mr. Christopher Heath, London.

PUBLIC MEDICINE. — President, Dr. E. P. Lachapelle, Montreal.

OBSTETRICS AND GYNECOLOGY. — President, Dr. William Japp Sinclair, Manchester.

PHARMACOLOGY AND THERAPEUTICS. — President, Dr. D. J. Leech, Manchester.

PATHOLOGY AND BACTERIOLOGY. — President, Mr. Watson Cheyne, F.R.S., London.

PSYCHOLOGY. — President, Dr. R. M. Bucke, London, Ont.

OPHTHALMOLOGY. — President, Mr. Edward Nettleship, F.R.C.S., London.

LARYNGOLOGY AND OTOTOLOGY. — President, Dr. Greville Macdonald, London.

ANATOMY AND PHYSIOLOGY. — President, Dr. Augustus D. Waller, F.R.S., London.

DERMATOLOGY. — President, Mr. Malcolm Morris, London.

PROVISIONAL PROGRAMME.

Wednesday, August 18th to Thursday, August 26th.

Meeting of the British Association for the Advancement of Science, at Toronto.

Thursday, August 26th to Monday, August 30th.

Excursion for Members and Guests of the British Association, from Toronto via Niagara, Kingston, The Thousand Islands, Ottawa, etc., to Montreal.

Monday, August 30th.

Meeting of the Canadian Medical Association at Montreal.

British Medical Association.

Tuesday, August 31st.

12.00 A. M. — Service in the English Cathedral.

2.30 P. M. — Windsor Hall: Opening ceremonies and addresses of welcome.

3.00 P. M. — Address by the President-Elect, T. G. Roddick, M.D., M.P.

4.00 P. M. — Garden parties, excursions, around the mountain, etc.

9.00 P. M. — Soirée at Laval University.

Wednesday, September 1st.

1.00 P. M. — McGill University: Opening of Sections.

3.00 P. M. — Windsor Hall: Address in Medicine, by Dr. Wm. Osler.

4.00 P. M. — Excursion down the St. Lawrence, etc.

9.00 P. M. — Sohmer Park: Conversazione and dance.

Thursday, September 2d.

9.30 A. M. — McGill University: Sectional meetings.

1.30 P. M. — Lunch on the mountain.

3.30 P. M. — Windsor Hall: Address in Surgery, by Mr. T. Mitchell Banks.

4.30 P. M. — Excursion across the Island, etc.

7.45 P. M. — Annual Dinner of the Association, Windsor Hall.

Friday, September 3d.

9.30 A. M. — McGill University: Sectional meetings.

3.00 P. M. — Windsor Hall: Address in Public Medicine by — and concluding General Meeting.

4.15 P. M. — Excursion to St. Anne's and down the Lachine Rapids.

9.00 P. M. — Soirée at McGill University.

Saturday, September 4th.

Excursions to Ottawa, Quebec, Kingston, St. Agathe, Lake Memphremagog, etc.

ARRANGEMENTS FOR AND OPPORTUNITIES AFFORDED TO GUESTS OF THE ASSOCIATION.

American guests attending the meeting of the Association will probably be able to obtain the ticket to Montreal and return at the rate of one fare and one-third, a rebate being given in Montreal upon presentation of the return ticket.

In Canada they will be able to travel to nearly all parts of the Dominion, from Halifax on the one hand, to Victoria, B. C., on the other, at half rates for the single journey, and single rates for the return journey.

During the meeting there will be several afternoon excursions in the neighborhood of Montreal, given to them by the Montreal Branch of the Association.

Fuller particulars as to excursions will be afforded at a later date.

SOCIETY NOTICES.

THE ASSOCIATION OF MILITARY SURGEONS. — The seventh annual meeting of the Association of Military Surgeons of the United States, will be held in Columbus, O., May 25, 26 and 27, 1897.

AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION. — The initial meeting of this new Association will be held Thursday, June 3, 1897, at the College of Physicians, N. E. cor. 13th and Locust Streets, Philadelphia.

RECENT DEATH.

BENJAMIN EDDY COTTING, M.D., M.M.S.S., died in Roxbury, May 22, 1897, aged eighty-four years.

BOOKS AND PAMPHLETS RECEIVED

When Symptoms are Absent. By Thomas Jameson, M.D., Rochester, N. Y. Reprint. 1897.

Announcement of Summer Courses (1897) to be given at the Massachusetts Institute of Technology.

Two Cases of Early Atrophy of Muscles in Cerebral Disease. By F. G. Finley, M.D., Montreal. Reprint. 1896.

Fracture of the Scapula by Muscular Action Alone. By C. J. Edgar, M.D., North Hatley, P. Q. Reprint. 1897.

On Retroperitoneal and Perirenal Lipomata. By J. George Adami, M.A., M.D., Montreal, Can. Reprint. 1897.

Introductory Lecture on Hygiene, Public Health and Preventive Medicine. By Robert Craik, M.D., LL.D. Reprint. 1896.

Concerning the Present Condition of State Medicine in the United States. By Franklin Staples, M.D., of Winona, Minn. Reprint. 1897.

Ann Arbor: George Wahr. 1897.

Original Articles.

A CASE OF BRAIN CYST WITH JACKSONIAN EPILEPSY: OPERATION FOLLOWED BY RELIEF.¹

BY A. T. CABOT, A.M., M.D.,
Surgeon to the Massachusetts General Hospital.

THE following case is reported as a contribution to our knowledge of the pathology and operative treatment of epilepsy. The patient was an intelligent and good observer of his symptoms, thus making the clinical history reliable and full.

F. P. K., aged twenty-three, consulted me in the latter part of September, 1893, and entered the Massachusetts General Hospital for further observation and operation. He there had the advantage of careful consideration of his case by Dr. J. J. Putnam, to whom I am indebted for much assistance in my study of it. His history was as follows:

He had no tuberculous inheritance, but on his father's side there was some neurotic tendency. He had the usual diseases of childhood, having had measles the second time as late as 1891. He always lived in the country, and was a good scholar, leading his class at Exeter in 1889, and standing high in the Class of 1893 at Harvard. He never had a serious injury, but was struck on the top of the head twelve years before by a heavy stick which had been thrown up to knock down chestnuts. He was not stunned, but remembered that his head bled somewhat. He felt no after-effects of this blow.

In January, 1891, he first noticed an occasional feeling of numbness in the middle of the right thigh on the anterior surface. This was accompanied by a tickling sensation, and was so annoying that he would jump from his seat and slap and rub his thigh at the same time laughing in an excited manner; and this would be followed by a feeling of nervousness. These seizures appeared about once in three or four weeks.

In June, 1892, after a hard college year he went to Kansas, where the weather was hot and trying. He here had his attacks almost every day, and they soon began to be accompanied by contractions of the anterior muscles of the thigh and twitching in the abdominal region. His leg would become rigid, and would rotate back and forth involuntarily.

In August of that year he, for the first time, had a severe attack followed by general convulsions and loss of consciousness. This fit started as usual in the right thigh. After pinching and pounding the thigh, he ran a few steps to ward off the cramp, and fell to the ground on his right side. The right leg became rigid, while the foot was drawn sharply inwards (extreme talipes varus), and then the whole leg twitched convulsively. Then his head was drawn over sharply. In the last moment of consciousness he thought his neck and ankle would break, so strongly were they distorted. Consciousness was regained in twenty minutes. The attack was followed by vomiting. The next day he felt perfectly well. Soon after this he began to take bromide of potash, but in spite of this had occasional slight attacks.

On October 1st, after his return to college, he had another general convulsion. Through this winter he was able to keep on with his studies, but with occa-

sional attacks, which were, for the most part, controlled by the inhalation of amyl nitrite. The attacks now began to be followed by a feeling of paralysis and numbness in the right leg.

In the middle of March the paresis following the attack affected not only the leg but the arm and face on the right side. He finished his college course, but continued to have his attacks at intervals through the summer; and in the last one, in which he was prevented from having convulsions only by the prompt use of amyl nitrite, he had paresis of the leg, which came on slowly fifteen minutes after the attack, followed by a similar feeling in the face and then by a quick and complete loss of power in the arm. This condition lasted an hour or so. An hour and a half after the attack he had aphasia come on, lasting ten or fifteen minutes. His general health was good and his intelligence unimpaired.

We had here the history of a disturbance of nerve function beginning two years before, and at first affecting only the leg centre at the upper part of the fissure of Rolando. Gradually the irritation extended down along the fissure of Rolando to the centres of the abdomen, shoulder, arm and face.

The degree of functional interference with these centres was also gradually increasing until he had a temporary paresis of the muscles following each attack. As the irritation began to reach the shoulder centre, it had attained a sufficient degree of intensity to affect the sensorium and led to a general convulsion.

It was evident that some change was taking place in the motor areas indicated by the above symptoms, but it was not clear what the exact nature of the change was likely to be.

We had to consider the possibility of tumor, including cysts, tubercle and gumma, and also of some degenerative change in some way connected with the old injury, either through the irritation caused by a depressed spicula of bone, by an adhesion of the membranes, or by some change originating in an injury of the brain substance itself.

The absence of the severe pain so characteristic of the invasion of brain tissue by a tumor, and the slow development of the symptoms, led us to regard gliomatous or sarcomatous tumor improbable. The history lent no support to the supposition that we had either a gumma or a tubercular tumor. On the other hand, the history of an injury to the head was so clear as to lead us to attach importance to it in seeking a cause for our symptoms.

The localization was so exact that no doubt was felt as to the wisdom of an exploratory operation; and it was decided that, in the event of finding no gross lesion sufficient to account for the symptoms, we should remove the thigh centre, as being the one in which the disturbance had first showed itself.

I had previously written to Mr. Horsley in regard to this patient, and followed the plan suggested by him, by dividing this operation into two stages.

On October 5th, the fissure of Rolando having been mapped out with a cyrtometer, an aperture was made in the skull, nearly square in shape, measuring two and a half inches in each diameter, over the part of the brain believed to be affected.

On October 10th the patient was again etherized, the flap turned back and the dura opened. The brain bulged considerably through the opening and did not pulsate with normal vigor. It was also noticed that

¹ Read before the Boston Society for Medical Improvement, January 11, 1897.

the cortical portion of the brain had a yellowish color towards the upper part of the opening. Some doubt was felt as to which of two parallel sulci were the fissure of Rolando. Dr. Putnam stimulated the brain with a feeble electrical current, but, even after the patient was allowed to come considerably out of his ether, failed to produce any response over the yellow portion where the disease was presumably located. Finally, applying the electrode towards the anterior part of the opening, considerably in front of the presumably affected area, a twitch of the arm and shoulder and then of the thigh followed the stimulation. Puncture was then made with a trocar through the yellow area and a spurt of brownish serum escaped. A small opening was made into a cyst cavity, with a smooth, yellowish brown wall, about the size of a small pullet's egg, extending deeply into the brain towards the centre. No hardening or thickening anywhere could be detected in the walls of this cyst, and there were no papillomatous or other growths into it.

The size of the cyst made a removal of its whole wall a very formidable operation; and in the belief that it was probably a simple cyst, without malignant character, I decided to treat it by drainage in the hope of thus obliterating its cavity. Several large strands of loosely-woven silk were introduced as a drain, being brought out directly through an opening in the middle of the dural and skin flap.

The patient made a good recovery from this operation. The wick was removed on the third day, and he went home sixteen days later with everything solidly healed.

Until the middle of December (one month and a half) he had no epileptic symptoms. Then the aura was felt in the right thigh. From this time he had this sensation occasionally at varying intervals, sometimes as often as once a week and then again not oftener than once in three or four weeks. He continued to take bromide of potash at the rate of 40 to 60 grains a day.

Early in February (three months after recovery from the operation) he felt well enough to go West and begin work. In June he was working hard, and felt so well that he began to cut off the bromide; and when he got down to 35 grains a day, he began to have the aura more frequently. About the middle of the summer he began to notice that each time after the sensation of the aura he had a partial paralysis of the right arm and leg, appearing twenty minutes to half an hour after the aura and lasting about an hour. He now also began to have severe headache about the old scar and frontal region, accompanying the attacks.

In October, having been a month without any epileptic feelings, he was promoted and had harder work. On November 4th, for the first time since September 9th, he had a recurrence of the aura, and between that time and the 15th he had six attacks. He now began to have twitching of the right arm, shoulder, neck and face, and he also experienced a constant numbness in the right hand, foot and leg. In one of the attacks of November the paralysis following the aura lasted from four to five hours. The latter part of November he began to have a very confused feeling about the face during the attacks, and could not move his eyes, they being held rigidly. He now had trouble in noticing persons and things on his right, and some loss of hearing in his right ear. His condition finally compelled him to give up work; and early

in December, 1894, he came East and again consulted me.

It was evident from the nature of his symptoms and their gradual advance that he again had trouble in the old region, and it seemed probable that this was due to a refilling of the cyst.

He re-entered the hospital January 3, 1895. Examination at this time showed no change in the region of the scar. The pulsations of the brain were distinct. He was clumsy and sluggish in the movements of his right foot, but the grasp of his right hand was strong. His pupils were equal and reacted readily to light. The patellar reflexes were normal.

January 7, 1895. Operation under ether. The flap over the skull defect was reflected, and the dura mater was opened along the old incision. It was not adherent. As soon as the dural flap was lifted the brain began to bulge into the opening, and in a moment it gave way in the middle of a yellowish area which marked the site of the cyst. A spurt of thin, brown serum now burst through, the fluid being thrown out with some force. The outer wall of the cavity was freely cut away, and the cyst wall was seen to have the same character as at the last operation.

The size of the cavity seemed distinctly greater than at the previous operation. An attempt was made to separate and remove the cyst wall, which was soft, yellowish, very friable, and about a line thick. In the parts about the opening this thin wall could be readily separated from the brain tissue beneath it; but after the sides of the cyst were reached deeper in the brain, this separation was harder to effect, both on account of the friability of the wall and because it was more adherent to the underlying brain. The attempt was, therefore, abandoned, and a large wick of gauze was introduced for drainage through a good-sized hole in the middle of the skin and dural flaps. This wick was introduced merely as a temporary measure until arrangements could be made for more efficient and long-continued drainage. To provide for this I had some glass tubes made of the shape of a shirt stud, the stem of which was as thick as a No. 20 French catheter and was perforated by an opening of sufficient size for good drainage. One of these, just long enough to reach through the skin and dura into the cyst cavity, was introduced on the third day, when the gauze wick was removed. The escape of fluid was much more free through this tube than it had been along the wick, and it continued to be quite abundant for ten days, after which it began to sensibly diminish, and the cavity as explored by the probe began to grow much smaller.

The patient had no sensation of aura after the operation, and was up on the seventeenth day. He went home on the twenty-sixth day; but the button was not removed until the forty-fourth day, at which time the cavity of the cyst being entirely obliterated, it was taken out and the opening quickly closed.

The subsequent history of the case is perhaps best given by the following abstract from a letter from Mr. K., in December, 1896.

About April 1, 1895, I was appointed to a position as inspector of an extension of the water works in Lincoln—a position which gave me employment for about two months in the open air, and involved no intellectual strain. In June of that year (1895) I was in excellent health, and had felt no suggestion of the old epileptic aura for about

two months, and had taken no bromide or other sedative during that time. I then began to do a little studying preliminary to taking a course in physics at the Harvard Summer School. I almost immediately began to feel a slight return of my former sensations—a crawling numbness, if I may so express it, in my right shoulder and arm, and in the right side of my neck and face. The sensation was so very slight that at first I hoped I could finish the short course of study that I had undertaken in spite of it; but as the sensations rapidly became more frequent and more strongly marked, I concluded that I could not safely continue my work, and so gave it up after about three or four weeks.

Through the month of August I enjoyed absolute rest from mental work, and, as a result, enjoyed absolute immunity from these nervous sensations.

Meanwhile I had secured a position to teach school at Shrewsbury, Mass., and began my work there as principal of the high school, September 2d. For the first two or three weeks all went well, apparently, though the work was hard and the school a rather large one for one teacher. It soon began to tell on me, however, causing a return of the sensations of partial paralysis in my right shoulder, face and neck. With the exception of these sensations I felt very well indeed, and began taking bromide of potassium in the hope that I could keep up my school work till the end of the term at least, and not disappoint the committee. By the aid of the bromide I continued my work as principal for six weeks, and then resigned, as the sensations in the region of my right shoulder had become too decided to be longer disregarded. I returned to my home in Lincoln and worked about my brothers' greenhouses for a little over a month, stopped taking bromide at once, and after a week or two felt no further trouble in the region of my shoulder.

Late in November I took a position in an advertising agency in Boston as a solicitor, work which, though I detested it, kept me out of doors a good deal of the time and seemed to agree with my health very well, except that the continual walking apparently wore out my right foot, which ever since the last operation has not been normally sensitive. If I attempt to use that foot upon the pedal of a piano or upon the step of a carriage it is very liable to slip off, unless I watch it carefully, as I cannot tell by the feeling just where it is. In rising and moving away from a table, sometimes this foot catches against the leg of the table or chair; I am aware that it touches something, but in what direction to move it in order to disengage it I am unable to determine until I look down and see on which side of the table leg my foot is.

Apparently the circulation is slower in this right foot than in the left, for it feels the cold in winter much more keenly than the left one does. As far as I can tell, the condition of this right foot is neither better nor worse than it was when I left the hospital nearly two years ago.

About February 1, 1896, I came to Albany to do some mathematical work, which consisted in the reading, criticism and preparation of manuscripts for a text-book in geometry. It required close application, but involved no responsibility or worry, and I was able to do it successfully, working about seven hours a day from February 1st to the middle of June, and from the middle of August till the last of October. During this period I took no bromide, except a few doses when I was troubled with sleeplessness, and had only an occasional numbness, very slight, in my right arm, perhaps as often as twice a month. In general, since last February, I have enjoyed excellent health and have steadily gained in strength and vigor.

On October 28th I was married. Since my marriage I have been occupying the position of examiner in the office of the regents of the University of the State of New York. This position requires me to do seven hours' mental work daily, but that does not appear to be too much for my strength, as I am feeling better now than at any time for more than four years.

I have quoted this letter at length in order to give

a thorough idea of the condition following the operation, and to enable each reader to judge of the completeness of the cure. While we cannot be certain that future difficulty is not in store for him, it seems fair to accept this two years' immunity from anything approaching a really epileptic seizure as evidence that the cure has been more than temporary.

Cysts of the brain may be either traumatic, hydatid, or associated with the growth of a glioma. This was clearly not a hydatid cyst, as all of the characteristics of that form were wanting. Nothing suggesting the existence of a glioma could be made out in this case, and the duration of the symptoms made it improbable that a growth of that sort lay at the bottom of the pathological process. Unfortunately the bit of cyst wall removed was lost before reaching the pathologist, and was not examined. On the other hand, there was good reason to regard this cyst as of traumatic origin.

The fluid removed at the second operation was carefully examined, and found to consist of "mixed serum and blood." It was highly albuminous, contained much fibrin and was alkaline. The sediment consisted of normal and abnormal blood-corpuscles. Many of the latter had irregular and unusual forms, but their identity was established by their behavior with reagents and staining fluids. There were also many small, white, mononuclear cells (lymphocytes).

This examination shows the fluid to be of the character that would be expected in a traumatic cyst, and confirms that diagnosis.

In cysts of this character a hemorrhage of greater or less extent usually acts as the starting-point of this process, and the pressure of the fluid leads to the slow destruction and softening of the surrounding brain tissue, thus causing a gradual enlargement of the cyst cavity, which may go on for months or years.

It seems probable that the blow received on the head twelve years before may have caused the slight hemorrhage which served as a nucleus for this cyst to form upon. The slow growth of the cyst enabled the brain to adapt itself to the gradually increasing pressure until the motor centres were very considerably pressed upon by it. At the first operation, when their position was tested, they were found considerably anterior to the position where they might have been expected.

The gradual extension of the epileptic symptoms from the right thigh to the right side of the abdomen and finally to the arm and face would indicate that the original site of the cyst was probably near the motor centre for the thigh and gradually extended from there along the fissure of Rolando until it reached the centres for the abdomen, shoulder and face.

The proper surgical treatment of cysts of the brain is undoubtedly that advised by Mr. Victor Horsley in a personal letter to the writer, namely, to thoroughly excise the wall. This is especially true of cysts that have their origin in a gliomatous growth, and in such cases it offers the only hope of a lasting cure. It is almost impossible to determine in many cases whether any part of the cyst wall is gliomatous or not; and in this condition of uncertainty it is doubtless better to cut out the wall of all cysts when this is feasible.

It may sometimes happen that cysts will be encountered too large for such thorough removal of their walls, and in which the probability of a benign character makes their treatment by drainage desirable. It is well, therefore, that we should learn what can be accomplished by this method.

The case I have reported is especially adapted to throw light upon this question from the fact that after ordinary drainage by wick, maintained for but a few days, had failed to cure it, a more efficient and persistent drainage was followed by apparent success. It would seem important to keep up the drainage until the absolute obliteration of the cavity is accomplished. This obliteration is brought about primarily, I think, by the expansion of the brain when the pressure upon it is relieved. It fills again with blood and tends to return to its normal position. Finally, the healing of the walls together is accomplished by the proliferation of the neuroglia and of the connective tissue about the blood-vessels.

The effort to bring about this kind of healing requires long aseptic drainage, and for this purpose the form of tube used in this case has some advantages. The wide, flat rim rests firmly on the skin and, having no projection, is not disturbed by slight movements of the dressing. Its length can be arranged to just enter the cavity and not to project unnecessarily into it. It can be made of glass or metal, so as to allow of thorough cleansing. The slightly projecting lip on the inner end serves to steady it in the cavity and to prevent its slipping out.

CYST OF THE BRAIN.¹

BY J. W. ELLIOT, M.D.,

Surgeon at the Massachusetts General Hospital.

THE patient, a male negro, aged fifty-nine, was at the Massachusetts General Hospital in 1889 with a cardiac disturbance, which wholly disappeared. He had had syphilis in 1877.

On March 14, 1892, he re-entered the hospital under Dr. R. H. Fitz. The hospital record states that in June, 1891, he began to drop things with his right hand, and that it required great effort and attention to prevent dropping everything. A few days after the onset he found his right thumb and forefinger numb; this lasted seven days. Soon then the hand became decidedly weak. In September began the twitchings which have troubled him ever since. They began in the index finger, and at first were confined to the hand; now they sometimes extend to the shoulder. For the last week the paralysis has been complete below the wrist. At times the palm is sore and painful and sometimes hot. Except for the hand he is perfectly well.

Examination.—The patient is large, well developed and nourished. Pupils react equally. Tongue protrudes in median line. Right hand slightly edematous. No voluntary motions of fingers or wrist. Pronation and supination performed slowly and with little force. Flexion and extension fairly strong. No impairment in sensation. Moderate muscular atrophy in upper and forearm. Examination otherwise negative.

He had one or two attacks of twitching daily, lasting from half a minute to two minutes. The twitchings began with convulsive flexion and extension of the first and second fingers and of the thumb, together with abduction and adduction of the latter. Similar movements spread to the other fingers and then to the wrist. With two to ten quick, partial flexions and

extensions of the forearm (and sometimes of the shoulder), the whole seizure abruptly ended.

March 22d. Two to four attacks daily, more severe than before, involving the right leg and thigh, with jerking. No mental disturbance.

He was seen by Drs. Putnam, Walton and Carter. For about six weeks he was treated with large doses of iodide of potash, which seemed at first to modify the attacks somewhat. But he was discharged on January 4th with spasms but little less than at entrance, as regards frequency and duration.

He then came under the care of Dr. Jas. J. Putnam, as an out-patient; and on February 8th he was sent to the surgical ward for operation, with the diagnosis of a cerebral tumor involving the centre of the right arm. The spasms of the hand and shoulder had continued about twice daily, and he was beginning to stammer and to speak thickly and indistinctly. There was no change in the condition of the arm.

Operation, February 9, 1893.—A trephine was applied at a point calculated to be over the arm centre, and a two-inch button was removed from the left side of the skull. The dura was pale, bulging, but not pulsating. On opening the dura the fissure of Rolando was seen. The ascending frontal and parietal convolutions presented, bulging, as if from pressure from behind, being pale but otherwise normal in appearance. An aspirating-needle was inserted into the most prominent part of the brain; at a depth of about one-fourth of an inch it entered a cavity, and a few drops of rather viscid, clear, brownish fluid containing an occasional whitish flake ran out. A knife was then entered beside the needle, and an incision about one-fourth of an inch long was made in the brain substance, which allowed the escape of more clear fluid. The little finger passed into the opening, felt a cavity about the size of an English-walnut. The walls of the cavity were covered with gelatinous-looking granulations. The surrounding brain-substance seemed healthy. A small drainage-tube was placed in the cyst cavity and brought out through a hole in the flap.

The operation caused some shock, but he was in good condition the next day. The tube discharged clear fluid, and the dressing was done daily.

He continued to have two attacks of twitching daily, but they were less severe than before the operation. The wound did well, and he sat up on the fourteenth day.

On February 28th he was improving in every way; but the tube slipped out of the cyst in the night, and on the following afternoon he began to have difficulty in speaking, and complained of dizziness. The scalp became tense and bulging over the trephine opening. He had a severe spasm, beginning in the arm and extending to the right side. The tube was replaced, allowing the escape of a small quantity of clear fluid. The patient again improved steadily; but it required several days to recover from the effects of leaving the tube out.

March 5th. The patient was up and about and having an occasional spasm. There was no change in the condition of the arm.

March 12th. An attempt was made to remove the tube, but it was followed by the same bad results as are recorded on February 28th. The tube was therefore replaced, and the daily dressing continued.

March 23d. There is considerable improvement. He has one mild spasm every two days.

¹ Read before the Boston Society for Medical Improvement, January 11, 1897.

April 2d. He walks very well. The speech is more distinct. There is less stammering and less dizziness. Has had no spasm for six days. The discharge from the tube remains the same in quantity and character.

It seemed probable that this condition would continue for some time. On this account we determined to make another attempt to obliterate the cyst. Accordingly, a second operation was done on April 5th. The sinus was enlarged by an incision in the scalp about one and one-half inches long. The cyst cavity was found to be about the size of a walnut, lined with whitish, sloughing tissue and granulations. The depth was not accurately made out, from fear of injuring the brain. The sloughing tissue was dissected from the walls, and the cavity thoroughly cleared out. The whole wound was made V-shaped and packed with iodoform gauze.

There was no disturbance following this operation. The patient was up on the second day, and continued to improve. A slight spasm of hand occurred on the sixth day. The dressing was changed daily; and in fifteen days the sloughs had all come away and the cavity was lined with pale granulations.

April 21st. The patient talks well, but drags the right foot in walking. The cavity is packed lightly and is filling up with granulations.

April 26th. Patient had two severe spasms. Talks well, but forgets words.

April 30th. Patient has had one slight spasm in last four days. He was discharged from the hospital, as he desired to go home, and could have the dressing done at home.

I heard from his friends that he failed gradually after leaving the hospital, and died in about three months.

From the fact that this patient gradually failed and died after the cyst was practically cured, I do not feel at all certain that the disease was simply a cyst, but suppose rather that it may have been a cyst in a glioma, although the brain about the cyst seemed to be perfectly normal. One of the most interesting points in the case was the almost immediate recurrence of the symptoms whenever the fluid was allowed to collect in the cyst.

INCREASE OF INSANITY AND CONSUMPTION AMONG THE NEGRO POPULATION OF THE SOUTH SINCE THE WAR.¹

BY THOMAS J. MAYES, A.M., M.D.,

Professor of Diseases of the Chest in the Philadelphia Polyclinic, and Visiting Physician to the Rush Hospital for Consumption in Philadelphia.

DURING the last ten or fifteen years there appeared various contributions on the disproportionate increase of insanity and consumption among the negro population of the South since the close of the Civil War. This literature² emanates from the best minds in the

medical profession of the South; and, believing that it pertains to a question which is of the most vital concern to social science, and also believing that it will enlist the attention of every student who is interested in the physiology of man's development, and in the prevention and cure of disease, I have seen proper to bring it before this meeting for a full and free discussion. I believe that such a consideration of the facts and figures which are here presented will serve to set into a new light the mechanism of some of the most powerful factors which are engaged in the production and perpetuation of two of the most deadly enemies of mankind.

In speaking of the increase of insanity in the colored population of Georgia, Dr. Powell, Superintendent of the Georgia Lunatic Asylum, makes the following comments: "There has been a radical change in the susceptibility to certain diseases, notably insanity, phthisis and similar maladies in this class of our population, from which they were almost entirely exempt up to 1867. . . . The census of 1860 will show that there were only 44 insane negroes in the State of Georgia, or one insane negro in every 10,584 of the population, and consumption in the full-blooded negro was rarely seen. The census of 1870 shows 129 insane negroes in this State, or one to every 4,225 of the population. The census of 1880 gives 411 colored insane, or one to every 1,764 of the population; while in 1890 there were 910 colored insane, or one to every 943 of the population."

Dr. J. F. Miller, Superintendent of the Eastern Hospital of North Carolina, for colored insane, says: "From close personal observation, embracing a professional life of nearly forty years among the negroes, and from data obtained from professional brethren in different sections of the South, I have no hesitancy in declaring that insanity and tuberculosis were rare diseases among the negroes of the South prior to emancipation."

The Eastern Hospital of North Carolina was opened August 1, 1880, for the exclusive accommodation of the colored insane, and this same writer furthermore states that during the first year there were admitted 91 insane negroes, which number represents the accumulation of this class of patients in that State during the first decade and a half after the Civil War. In 1885 there were under treatment in this institution, 144; in 1890, 244; in 1895, 307, and in December, 1896, 377 insane negroes.

Dr. J. W. Babcock, Superintendent of South Carolina Insane Asylum, says: "We cannot lose sight of the fact that on the basis of the census, as compared with insanity in the whites, mental disease in the negro has arisen from one-fifth as common in 1850 to one-half as common in 1880 and in 1890."

Dr. Miller also states that in the hospital in his charge the average mortality from consumption since its opening to 1896 is 25 per cent. of the total number of deaths. However, the death-rate from this disease was much less in its early management. Thus, up to 1884, it caused 14 per cent. of the total number of deaths; while in 1895 it produced 27 per cent. of all the deaths, and this in spite of a reduction of the general mortality-rate.

Dr. Powell (*op. cit.*) says: "From observation and of the Negro of the South. By Dr. J. F. Miller, Superintendent of Eastern Hospital, Goldsboro, N. C. Published in North Carolina Medical Journal, November 20, 1896.

Private Correspondence.

¹ Read before the Section of Neurology and Medical Jurisprudence of the American Medical Association, at the Philadelphia Meeting, June 3, 1897.

² Report on the Increase of Insanity and its Supposed Causes. By Dr. T. O. Powell, Superintendent of the Lunatic Asylum of the State of Georgia, October 1, 1886.

Tuberculosis in Asylums. By Dr. J. W. Babcock, Superintendent of State Hospital for the Insane, Columbia, S. C. Published in American Journal of Insanity, October, 1894.

The Increase of Insanity and Tuberculosis in the Southern Negro since 1860; Their Alliance and Supposed Causes. By Dr. T. O. Powell, Superintendent of the Georgia Lunatic Asylum, November 21, 1895.

The Effects of Emancipation upon the Mental and Physical Health

investigation I am forced to believe that insanity and tuberculosis are first cousins, or at least closely allied. The sudden outburst of insanity with the colored race of the South came associated with tuberculosis, hand-in-hand, keeping pace one with the other; hence, in obtaining histories of cases as they are brought to our institution, the hereditary predisposition to consumption is carefully inquired into. The prognosis of phthisical insanity is unfavorable. I am not surprised at any time to find insanity in a family strongly predisposed to phthisis, and phthisis in a family strongly predisposed to insanity."

Dr. T. J. Mitchell, Superintendent of the Mississippi Lunatic Asylum (cited from Dr. Miller's able paper), states that among the negro patients of this institution the following number of deaths occurred in the years named: In 1892 there were 44 deaths, and 14 of these, or about 32 per cent., were caused by consumption. In 1893, there were 29 deaths, and 16 of these, or about 55 per cent., were caused by consumption. In 1894 there were 40 deaths, and 18 of these, or 45 per cent., were caused by consumption. In 1895 there were 35 deaths, and 11 of these, or about 31 per cent., were caused by consumption. In ten months of the fiscal year of 1896 there were 48 deaths, and 20 of these, or about 48 per cent., were caused by consumption. These data show that about 42 per cent. of the total number of deaths in this institution were caused by consumption during these years; and estimating the death-rate among the white population from this disease at 20 per cent., the death-rate among the insane negro population is 22 per cent. greater.

Dr. E. D. Boudurant, Assistant Superintendent of Alabama Insane Hospital (cited from Dr. Miller's paper), says: "During three years and nine months, beginning October 1, 1890, 295 deaths occurred among the 1,700 patients treated in this Hospital. Of the 179 deaths among white patients, 51, or 28 per cent., were due to tuberculosis; of 116 deaths among negro patients, 49, or 42 per cent., were due to tuberculosis. In addition to this, a study of our clinical records discovers the fact that in the colored race the disease assumes a much more active and rapidly progressive form, the average duration of fatal cases being markedly shorter in the negro."

Dr. W. H. Barnes, First Assistant Physician in Arkansas Lunatic Asylum, states, in a private communication, that neither insanity nor pulmonary consumption were especially prevalent among the negroes while they were slaves.

Dr. R. J. Preston, Superintendent of the South-Western Hospital of Virginia, says, in a private communication, that there has been a great increase in both insanity and phthisis among the negro population since emancipation.

Dr. Jas. D. Moncure, Superintendent of the Eastern Hospital of Virginia, informs me, in a private communication, that the health of the negro with regard to insanity and phthisis was very much better before emancipation than since. Before that time there were about 60 insane negroes in the asylums of Virginia. Now (1896) there are over 1,000. In all hospitals the insane seem readily to contract tuberculosis; and this is a frequent cause of death among the insane.

From the foregoing the following conclusions may be safely drawn: (1) that insanity and consumption were comparatively infrequent in the negro race be-

fore the war; (2) that both of these diseases have disproportionately increased in the same race since the war; and (3) that in all probability the causes which give rise to one of these diseases also produce the other.

Now what is the cause for this rapid and remarkable transformation in the health of these people during the short period of three decades? Why should insanity and consumption develop side by side, and at an equal pace, and why should the former frequently precede the latter in the same individual? Are these diseases acquired through contagion, or are they due to other conditions and influences inherent in the changed environment of this race? These are questions which appeal to the very root and marrow of this matter; and until we solve them we cannot hope to grapple successfully with either the cure or prevention of the diseases under consideration.

First, in regard to contagion, it is needless to say that even at present there is not a trace of well-grounded suspicion that insanity is acquired through contagion; and hence nothing need be said on that side of the subject. In the next place, is there any evidence to show that consumption's contagion was lying dormant before the war, and that it sprang into sudden and most virulent activity after the close of this period? So far as I know there is none, and aside from the untenability of such a position Dr. Powell testifies (*op. cit.*) that the opportunity for contagion was most favorable before the war. "It should be remembered," he says, "that up to the war and during the war the negroes were the principal nurses for the consumptives of the South. They washed the spittoons, bedding and clothing of the consumptives, swept and dusted their rooms, and in many instances slept in the rooms with them—literally living with them night and day, and were more exposed to the tubercle bacillus than now as a general thing: still they resisted the disease."

I think the whole question of the origin of consumption will be solved most easily if we study the causes which lead to both insanity and consumption together; for though on superficial inspection these two diseases have nothing in common, yet deeper study teaches us that the former is a perfect analogue of the latter. During the last ten years I have been engaged in collecting material—clinical, experimental and pathological—which demonstrates that pulmonary consumption is not primarily a disease of the lungs, but a secondary manifestation of impaired integrity of the nervous system in general, and of the pneumogastric nerves in particular.

This view did not originate with me, for in 1842 Cheneau attributed this disease to disordered pneumogastric innervation. In 1850 Dr. J. C. Holland defined pulmonary consumption as a disease of the nervous system. In 1862 Dr. Laycock stated that defective pneumogastric innervation consequent upon a loss of cerebro-spinal power was a very common predisposing and exciting cause of phthisis. Dr. Clifford Allbutt said in 1871: "The more I study this, the more I am satisfied that the lung mischief is also a neurosis—by which I mean that the lesion is one not originating in the local tissues, but in the nervous system." In 1891 Dr. T. S. Clouston delivered a course of lectures in which he stated that facts "seem to show that if tuberculosis cannot itself be called a neurosis, it is in most cases dependent for its exist-

ence on a trophic neurosis, or has the closest affinity to it."

There is also a richness of clinical material scattered throughout the literature of medicine which confirms the pathological view that phthisis is a neurotic disease. Thus, in my *brochure*³ on "Pulmonary Consumption a Nervous Disease," I collected and tabulated a large number of cases of phthisis in which the pneumogastric nerves were compressed by tumors, aneurisms, or otherwise disintegrated, prior to the onset of the disease in the lungs. In other papers⁴ since published, I believe that I have succeeded in demonstrating the following propositions concerning the close affiliation that exists between insanity and pulmonary consumption: (1) that both of these diseases are most liable to occur at the same age-period, that is, between twenty and thirty years; (2) that the family which is burdened with one is also liable to produce the other; this liability being greater in the case of insanity than in that of phthisis; (3) that they are both closely related in personal and family history to idiocy, hysteria, epilepsy, asthma, and to other diseases of the brain and the spinal cord; (4) that they are both produced by syphilis, alcohol, overwork, business vicissitudes, domestic trouble, mental anxiety, grief, disappointment and excesses of all sorts — in fact by any agent or influence, such as those named, which vitiate the brain or the nervous system; (5) that the insane, the idiotic, the epileptic, the hysterical, the asthmatic and the members of their families, are from three to eight times more prone to become phthisical than persons who are not burdened in the same way; and (6) that those who are confronted by a new and higher civilization, and who are compelled to adjust themselves to these new relations are excessively liable to fall victims to pulmonary consumption.

Let us now consider the question of the increase of insanity and of pulmonary consumption among the negroes in the light of these deductions, and see what interpretations can be given to the origin of these diseases. And in the first place we will discuss the effects on the nervous system which are wrought by a struggle between a higher and a lower civilization.

At the very outset it must be conceded that a struggle for existence even under the most uniform and favorable conditions is accompanied by considerable wear and tear of the body. What, then, is the outcome, if a lower is precipitated into the midst of a higher civilization? Civilization is an accumulation of force; and the older and higher the civilization the greater is its momentum. It is the meeting of two forces which differ in power and rate of motion. The higher civilization, backed by its many thousand years of organization and experience, cannot, except to its own detriment, change its upward career; and hence the lower must for the sake of self-preservation adapt itself, so far as this is possible, to the course and changes of the higher movement. The effort of adjustment between the two may be compared to an animal which is confronted by a new geological era to which it must either adapt itself or forfeit its existence. The mandates which come from the changed geological environment to the animal are no less real and imper-

ative than those which come to the negro from his changed surroundings.

If we fully realize that the negro came out of the darkness of Egypt and was brought face to face with a civilization — with its education, knowledge and inventions; its advanced sanitation; its innumerable arts, sciences and manufactures; its multiplicity of industries and employments; its burning life-struggles; and its proneness to vices and excesses of all sorts — it cannot surprise any one that in many instances he is unequal to the task of adjusting himself to these, and falls a prey to disease. The point of greatest importance here is the fact that the brunt of the battle in this contest falls on and vitiates the brain and nervous system, since these structures are the instruments through which his efforts are chiefly made to bring himself in harmony with his changed relations. He, therefore, becomes insane and phthisical because his nervous system is undermined by and disintegrates under strains and burdens which he is unable to resist or to counteract.

In regard to the effects of a changed social environment on the negro, Dr. Miller (*op. cit.*) says:

"The untutored savage, owing to a nervous organization less sensitive to his environment, can exist and be healthy in mind and body under conditions that will seriously affect the man of finer sensibilities from culture and education. The negro in slavery had 'no thought for the morrow,' wherewithal he should be fed and clothed. Nor did the claims of family press upon him to worry and affect his mind; no ambitious hopes stirred his brain as to the possibilities of his future; but 'far from the madding crowd's ignoble strife' he spent his quiet, humble life in his little log cabin, with his master to care for every want of self and family, in sickness and in health.

"It is an undisputed fact, known to our Southern people, that no race of men ever lived under better hygienic restraints. . . . Their habits of life were regular; their food and clothing were substantial and sufficient, as a rule; and the edict of the master kept indoors at night and restrained them from promiscuous sexual indulgence and the baneful influences of the liquor saloon. In sickness he was promptly and properly cared for by physician and nurse. Freedom came to him, and a change came over his entire life. Under his former manner of living he enjoyed a wonderful immunity from brain and lung trouble; and I confidently assert that the germs of these troubles came to the same man and race in consequence of his changed environment and the manner of his life which followed.

"In his ignorance of the laws of his being, the functions of citizenship, and the responsibilities and duties which freedom imposed, demands were made upon the negro which his intellectual parts were unable to discharge. In his former condition none of these things disturbed his mind. Immediately the restraining influences which had been such conservators of healthfulness of mind and body were removed, thousands left the quiet homes and regular life of the country for crowded and badly ventilated houses of the towns. These were often located in the midst of unhealthy surroundings, their occupants without regular employment eking out a precarious existence."

Dr. W. B. Barnes (before cited) says that the causes of the increase of insanity and consumption among the negro population are deprivation, exposure,

⁴ Pulmonary Phthisis in Relation to Insanity, etc. Medical News, July 16, 1892.

Toxicosis of the Nervous System as a Cause of Consumption. Journal Nervous and Mental Diseases, November, 1896.

poor hygiene, difficulty of self-preservation, and mental anxiety.

Dr. R. J. Preston (before cited) states that the increase of these diseases among the negro since emancipation is due to the cares of life which are thrown on them, bad hygienic surroundings, crowding together, and no restraint on dissipation and vice.

Dr. Jas. D. Moncure (before cited) states that this increase is owing to crowding into cities, improvidence in living, and exposure to contagion.

All the testimony goes to show, too, as has been intimated already, that the vices of alcoholism and syphilis are freely acquired by these people; and there is abundant evidence to prove that both of these influences have a special predilection for destroying the integrity of the nervous system, and in this way to bring about insanity and phthisis.

Touching on these infirmities Dr. Powell says (*op. cit.*): "The ultimate results of alcoholic intemperance in this race is to be apprehended, perhaps, more than from any other influence, from the fact that there is a tendency to alcoholic intemperance, not only on the part of the men, but also on that of many women. Could we be justified in expecting a perfect mental and physical organism from parents both of whom were drunkards?"

He also says that "the direct and indirect effects of syphilis constitute one of the leading factors in the causation of insanity in the colored race. The large number that are tainted with syphilis in some sections is really alarming. I have ascertained from reliable sources that on some of the large plantations where there is a great number of negroes, there are few of the adults that are sound or free from the taint of syphilis. I have conferred freely with quite a number of physicians who were actively engaged in general practice before the war, and they seem to be fully agreed in the statement that secondary or tertiary syphilis was almost unknown in the country negro at that time.

He also gives the following very interesting account of the ravages of consumption among a settlement of negroes on three adjacent plantations in the Southern part of Georgia, and which was communicated to him by Dr. J. C. Patterson, in whose experience it occurred. Prior to the war these negroes enjoyed remarkable mental and physical health: Consumption, insanity and similar wasting diseases were altogether unknown among them. At the time of their emancipation there were upon these three plantations, including children, between 400 and 500 as healthy individuals as could be found, and free from all hereditary taint or tendency to any disease whatever. The negroes, as a rule, remained on the plantations where they were born. It was not long, however, before syphilis appeared among them; and it gradually spread over these plantations, the disease in nearly all cases going into the tertiary stage. Some ten or fifteen years later consumption and insanity began among the adults, many of their children died from scrofula and tuberculosis, and it was the exception rather than the rule that the children lived. Bodily deformities and idiocy were frequent among them.

Viewing the present condition of the Southern negro, then, from the standpoint of his changed surroundings, and taking into consideration the structure of the body which is specially implicated in this

change, it is perfectly obvious why insanity should develop as a necessary sequence in this soil. Upon the same ground, and upon no other, can we explain why pulmonary consumption should follow in the wake of insanity, and also increase in frequency. The truth is that those who were able to realize all the factors which would be called into activity by this environmental change of the negro could, at the time it was made, have foretold the inevitable results which are now but too evident to every one. It is a repetition, in part at least, of what happened, and happens now, to the aborigines of North America, Australia, and New Zealand, who, in their unequal warfare with modern civilization, have been, and are being fast decimated and exterminated by pulmonary phthisis.

THE NEW LOCAL ANESTHETIC, HOLOCAIN.

BY HASKET DERBY, M.D., BOSTON.

In an article¹ on "Certain Dangers attending the Use of Atropine," published a few years ago, I endeavored to call attention to the possible danger of increasing intra-ocular pressure connected with the employment of the ordinary mydriatics. The well-known fact that, in glaucoma, dilatation of the pupil increases and contraction of the pupil diminishes intra-ocular pressure long since led to the observation that the instillation of atropine and allied drugs might produce an attack of glaucoma in an eye predisposed to this disease. This observation was also found to hold good in regard to homatropine and even cocaine. But with the latter agent, used as it so generally is for the purpose of producing local anesthesia, the question of possible ill effects assumes peculiar importance. And, in point of fact, its employment for minor operations on the eye, in the case of patients who have arrived at or passed the period of middle age has been seriously hampered by the foregoing consideration.

Other disadvantages are, moreover, found to occasionally attend the instillation of cocaine. General faintness, dizziness, and even vomiting have from time to time been known to occur. Symptoms of cardiac disturbance, depending no doubt on some peculiar idiosyncrasy, are met with in some individuals.

Search has therefore been made for a local anesthetic that should be free from the disadvantages of cocaine. But none of the preparations experimented with have thus far proved wholly satisfactory. For one of the more recent of these, eucaine, it has been claimed that no pupillary enlargement, and therefore no increase in intra-ocular pressure, follows its use. But it causes local irritation, and therefore cannot be employed in inflammatory affections. And its repeated application has been found to finally give rise to pupillary dilatation. It offers no advantages over cocaine, and possesses peculiar drawbacks of its own.

In the January number of his *Centralblatt*, Professor Hirschberg announces the receipt of a new local anesthetic, to which he at first gave the name of "amidin." He found its anesthetic effects on the eyeball to be prompt and entire, no local irritation and no pupillary dilatation following its use. He used it with success in the extraction of a traumatic cataract, the presence of which had already given rise to inflammation.

¹ Boston Medical and Surgical Journal, December 28, 1893, p. 640.

The February number of the same magazine contains a full chemical account of the new substance. Without going into particulars, it is sufficient to say that it is closely allied to phenacetine. It has a powerful local anesthetic action, and is highly poisonous if administered internally, even in minute doses. No local poisonous effect has been noted. It is soluble in boiling water, and should be dissolved in a porcelain vessel, as it causes glass containing an alkali to lose a portion of the latter, which clouds the solution. It has finally been baptized with the name "holocain." The experiments at Hirschberg's clinic were continued, some forty-five cases having been subjected to its action. Anesthesia came on in from fifteen seconds to a minute, and lasted ten minutes. The instillation of holocain was accompanied by a slight burning sensation, no greater than that produced by cocaine. The dryness of the corneal epithelium produced by cocaine was here wanting. No pupillary enlargement and no effect on the accommodation were observed.

It was, moreover, found that holocain could be used in cases where cocaine was either contraindicated or failed to work, as, for instance, where there existed a considerable inflammation of the conjunctiva bulbi, attended by swelling. Its action was here entirely successful.

The solution of holocain needs no sterilization, being in the strength of one per cent. itself bactericidal.

Holocain possesses strongly poisonous properties, acting thus in one-fifth the strength of cocaine. When instilled in the conjunctiva no injurious effects have been observed.

In this new agent, then, we have a remedy that is likely to supplant cocaine in many cases of ophthalmic surgery. Among its advantages may be reckoned the following:

- (1) It does not enlarge the pupil.
- (2) Does not affect the accommodation.
- (3) Does not increase intra-ocular pressure.
- (4) Promotes antiseptics.
- (5) May be used when cocaine is contraindicated.

Per contra, its poisonous nature prevents it from being used subcutaneously. And, as it does not contract the vessels, operations done under its influence are likely to be attended by more hemorrhage than those performed under cocaine.

Dr. Tauber, who was the first to give an account of the chemistry of holocain, says that it belongs to the class of ethenylamidins, its proper cognomen being p-diäthoxyäthenyldiphenylamidin. It is manufactured at the color-works of Meister, Lucius & Brüning, at Höchst-on-Main. Through the kindness of Mr. Davidson of the Theodore Metcalf Company, I was enabled to obtain an early specimen, and at once commenced its use myself, begging at the same time some of my colleagues to employ it and give me the results of their experience.

It has, up to the date of this writing, May 26th, been used in six operative cases and in ten others. The operations embraced three extractions of senile cataract, one of a dislocated lens, and one discission. Anesthesia was rapid and satisfactory in all these cases, the main contrast with cocaine being the slight flushing of the eyeball. In one case of trachoma, in which Dr. Standish did expression, anesthesia did not come on for over seven minutes, but was then complete. In the ten remaining cases holocain acted as cocaine would have done, save that there was no effect on the pupil.

Since writing the above, an article by Drs. Heinz and Schlösser has appeared in the *Klinische Monatsblätter* for April. They have been working with holocain for the past four months. The foregoing statements are, in the main, corroborated. In their experiments one to two drops of a one-per-cent. solution generally brought about entire anesthesia in from forty to fifty seconds. When a second application was made, forty seconds after the first, entire loss of sensation invariably followed in thirty seconds more. The duration of the anesthesia is at least ten minutes. After the opening of the anterior chamber a second application was found to affect both iris and ciliary body, an iridectomy in a case of acute iritis causing no pain. This effect on the iris I, too, have observed. I had used holocain in a simple extraction of senile cataract, but finding it impossible to clear the pupil I was obliged to remove a small piece of the iris after the operation was otherwise completed. No holocain had been instilled since before the operation; and yet the patient, a nervous and apprehensive woman of seventy-two, suffered absolutely no pain.

In view of all this, it would seem that, with our present knowledge, holocain is likely to take the place of cocaine in ophthalmic surgery, except in cases where subcutaneous injection is required.

Clinical Department.

A CASE OF HYPOSPADIAS.¹

BY HOWARD A. LOTHROP, A.M., M.D., BOSTON,
Assistant in Anatomy, Harvard University; Surgeon to Genito-Urinary
Department, Boston Dispensary.

THE condition known as hypospadias is a congenital malformation of the urethra, due to arrested development, whereby there is more or less deficiency of the floor of the urethra. During the first few weeks of the life of the embryo, the sexes cannot be differentiated; in the fifth month, however, not only has the sex been determined, but also have the genital and urinary organs become completely developed. All embryos start with certain common fetal structures, the after development of which, according to the sex, will determine the physiology, and, what concerns us in particular, the morphology of the region in question.

The urethra is formed by the fusion in the median line of two parallel ridges, the free edges of which unite so as to make a canal. As would seem natural, the vesical end of the urethra is formed first, followed in succession by the prostatic, penile and glandular portions. The great bulk of the penis is made up of the corpora cavernosa which are practically never entirely wanting, so that from the position of the corpus spongiosum we can say that the roof of the urethra is always present, or at least what would correspond to it, and our malformation or defect concerns the floor of the canal. Embryology teaches that arrest of development taking place before about the eighth week will give a urethra complete only as far as the membranous portion, and that the glandular portion is completed during the fourth month, hence, in any given case we can determine approximately when the formation of the urethral canal ceased to progress.

¹ Read before the Boston Society for Medical Improvement, January 11, 1897.

These degrees of malformation have been classified by the following self-explanatory terms :

- (1) Glandular or balanic.
- (2) Penile.
- (3) Scrotal: peno-scrotal, perineal.

The anatomical peculiarities of the varieties will be considered only in the merest outline. It will be understood that the glandular variety must be the most frequent, and at the same time the source of the least inconvenience, and, on the other hand, that the scrotal variety is attended with the greatest deformity and most annoying consequences. The scrotal variety has repeatedly given rise to doubt as to the sex in so-called hermaphrodites. Of great practical importance in the consideration of the methods of treatment is the position and development of the rest of the penis. In the *glandular* variety, the most apparent change, aside from the absence of the floor of the urethra, is the breadth of the glans penis, and the redundant prepuce on the dorsum. In addition to the above defects, the *penile* variety presents a more or less marked curve of the penis, concave below so that the glans approaches the scrotum according to the degree of malformation. In the *scrotal* type, the penis is most curved, and often so small as to be concealed between the folds of skin covering it above, and extending to the cleft scrotum below and on either side. This penile curvature is due not only to the absence of a portion of the corpus spongiosum, but also to a lack of development of the lower portion of the corpora cavernosa. Consequently, running along the underside of the penis is a firm band or cord of fibrous tissue, which fails to distend when the organ is filled with blood, and thus the deformity is more marked when erection takes place.

Orth² states that one in every three hundred males is subject to hypospadias, and that many of the commoner variety (glandular) never come to our attention, unless for some other complication, not aware that any deformity exists, for they suffer no inconvenience.

Heredity.—The history of the case here reported would lead us to think that heredity was of some importance in etiology.

Symptoms.—The symptoms relate to the deficiencies and inconveniences in carrying out the functions of *micturition, copulation* and *fecundation*.

(1) The glandular type interferes with none of these functions.

(2) The penile type is more or less important, according to the amount of defect. The penis must be raised in order to guide the stream of urine, coitus may be possible if the penis is not too much curved, and the power of fecundation will depend on the location of the urethral orifice. These two types are most amenable to treatment.

(3) The scrotal type precludes the idea of coitus or fecundation, and micturition causes great inconvenience. The patient must squat to perform that function in order not to wet the clothes, and even then the stream is broken into a spray which wets the parts so that frequently a troublesome eczema exists.

Incontinence is not a feature of these lesions, because the urethra is usually completed to a point distal to the constrictor urethrae muscle.

Treatment.—The earlier surgical methods attempted for the cure of hypospadias were absolute

failures. They consisted mainly in efforts to form a canal by means of a trocar or hot iron, passed subcutaneously on the under side of the penis from the glans to the point of urethral opening. Since 1861 the ingenuity of surgeons has been directed toward establishing a urethral canal by means of flaps obtained from various sources. In 1869 Thiersch devised a method for the cure of epispadias, which Anger made use of five years later in a case of hypospadias. The method of Duplay, quoted in most text-books, seems to be the favorite, but it is open to many objections, and failures are common. Flaps from the scrotum are unsatisfactory, both on account of their structure and hairy surface. Abdominal flaps are liable to contain hairs and are difficult to manage. Van Hook³ has recently devised a method of canalization and the introduction of an epithelial lining derived from the prepuce, but this method has not had sufficient trial to recommend it.

It is not easy to decide when it is best to operate. It is difficult to succeed in early operations on account of the diminutive size of the parts, and the almost unavoidable sepsis consequent on urine contamination, but, on the other hand, if a canal is once established, it is said that the organ develops more satisfactorily. Operation on the adult is more frequently attended with success, for it is easier to keep the urine from coming in contact with the field of operation. In children, the course of the urine has been deflected by means of perineal section. The patient or his parents should thoroughly understand beforehand the difficulties of the operation, that treatment will extend over several months, that several operations may be necessary, and even then absolute failure may result.

Of 20 cases operated on in the Czerny clinic by different methods, 52 operations were performed, and then the results were only as follows: cured, 7 cases; partially cured (fistulae remaining), 11 cases; absolute failures, 2 cases.

Cases operated upon at the hospital of the University of Pennsylvania required three or four operations.⁴

In considering these various methods, that devised by Thiersch seems to offer the best chance of success in the penile type. Comparatively extensive raw surfaces are overlapped, and rapid primary union is more apt to follow and remain firm than where smaller surfaces are approximated. It is absolutely essential to maintain asepsis, and to keep the parts dry and at rest. Failures are due to sepsis and swelling of parts, with consequent sloughing of flaps, tearing out of sutures, with consequent fistulae, or even no improvement whatever.

The following case will serve as an example of the peno-scrotal type, treated successfully by the Thiersch method. The operation was performed by Dr. M. H. Richardson, at which I was allowed to assist and then care for the after-treatment.

J. B., twenty-three years of age, clerk, was a young man in perfect health. Concerning the family history, he states that his father has a glandular hypospadias; his cousin, nineteen years of age, and his brother, twenty years of age, have the peno-scrotal type.

Five years ago, an attempt was made to construct a canal through the glans penis by the usual method, but the attempt failed. Two years ago, an operation was performed for straightening the penis, with con-

² Orth: *Pathologische Anatomie*.

³ Van Hook: *Annals of Surgery*, 1896, xxiii, 378.

⁴ *American Text-Book of Surgery*.

siderable success according to the patient's statement.

At the time of the present operation, the local condition was as follows: On inspection, the penis was somewhat smaller than the average and presented a curvature (convexity upwards) which was a little exaggerated over the normal. This curvature was increased when the organ became erected, but not sufficiently to interfere with coitus. The glans penis was broad and flattened below, and surmounted above and laterally by a redundant prepuce. There was no frænum or prepuce on the under side, but there was a shallow groove, corresponding to the upper wall of the urethra. The skin of the penis was abundantly developed and could be raised in folds. On the under surface, in the median line, was a linear scar about two inches long, across which were several short scars. Corresponding to the dorsal wall of the urethra, the skin was pink in several places, more delicate in struc-

ture, and was probably an altered condition of mucous membrane. The corpora cavernosa were soft and compressible, but in the median line below and between, could be felt a small fibrous cord. The urethral opening was in the median line exactly at the peno-scrotal angle. The scrotum and testicles were normal, as was also the skin about the urethral opening.

(1) To straighten the penis. On the under surface make one, or possibly two, transverse incisions so as to sever the fibrous cord which corresponds to the urethra, and in certain cases this incision must be carried into the substance of the corpora cavernosa. The penis is then forcibly stretched and we thus obtain a diamond-shaped wound (Fig. I),⁶ which is to be closed longitudinally (Fig. II).

It is best at this step to establish a canal through

ure, and was probably an altered condition of mucous membrane. The corpora cavernosa were soft and compressible, but in the median line below and between, could be felt a small fibrous cord. The urethral opening was in the median line exactly at the peno-scrotal angle. The scrotum and testicles were normal, as was also the skin about the urethral opening.

The inconveniences suffered by the patient were slight. At each micturition, the penis had to be raised, and the stream was fairly compact; but if he was not very careful the parts would become wet. Coitus was possible, and the ejaculations took place in the normal way; but the mechanical conditions were such that the seminal fluid could never enter the vagina. With the idea of correcting this deficiency, the patient sought operation.

The problem in these cases is (1) to straighten the penis, and then (2) establish a canal, and, in order to

make the description complete, the accepted method of straightening the penis will be described briefly.

(2) To establish the canal by the Thiersch method. An incision, 1, 2 (Fig. IV), is made, parallel to and about half of an inch from the median line, extending from the glans penis to a point opposite the urethral opening. Incisions 1, 3, and 2, 4, make a rectangular flap of this (a), which is dissected up with the line of the urethra (3, 4) as a base. The second flap b is twice as broad as flap a, with its free edges at 5, 6, parallel and close to the edge of the urethral groove. Incisions 5, 7, and 6, 8, are carried well

⁶ These figures have been suggested by other diagrams, and by the peculiarities of the case in question.

around to the side of the penis. After flaps *a* and *b* have been dissected up, a gum-elastic catheter is to be inserted into the bladder and flap *a* reflected over it so that the cutaneous surface is in contact with it and the raw surface exposed to view. This flap is held in place by fine silk sutures passed as follows (Figs. V and VI): The ends of the silk are threaded with small round needles, both of which enter the side of the urethral groove at *c* (Fig. VI), passing from the raw to the cutaneous surface, then transtix flap *a* near its free edges, passing from cutaneous to raw surface, and finally both needles pass through flap *b* at *d* (Fig. VI and V). These sutures are placed close together and rather loosely tied. Flap *b* is then drawn over so as to close the wound (Fig. VI and VII).

It is generally recommended to close the urethral opening, and to connect the distal end of the new canal with the previously formed glandular canal at a subsequent operation; but in this case it was decided to make the proximal connection at once. The edge of the urethral opening was denuded and flap *a* sutured to the free edge of the floor of the urethra and the line of suture covered with flap *b*, so that there was no direct communication. Remembering that glandular hypospadias never interferes with the function of the penis, no attempt was made to restore that part of the canal, although this should be carried out when the penis is straightened.

The catheter was maintained by the "jury-mast" contrivance (Fig. VII), the silk threads running from the tip of the catheter to a circular rubber ring about three inches in diameter fastened at the base of the penis, which also served to retain the dressing in place.

Convalescence. — Before the operation, the bowels were thoroughly evacuated, and then the patient kept on a light diet for nine days, when they were moved for the first time by enema. Opium suppositories and bromide solutions were used with perfect success to avoid erections. The syphon worked perfectly, and at no time was there any escape of urine around the catheter. On the fourth day, the deep sutures were removed. On the sixth day, on account of a slight urethral discharge, the bladder was irrigated with a solution of boric acid so as to cleanse the inside of the catheter, which was then withdrawn *just* beyond the constrictor urethrae muscle, and the urethra irrigated with the catheter in this position. This procedure was repeated on the tenth day. On the seventh day all stitches were removed, and the wound was apparently healed. The catheter was removed for the first time on the sixteenth day, without having caused any particular discomfort. There had been neither pain nor tenderness except at the site of the original opening, where it was slightly tender on the third and fourth days. The wound remained perfectly dry at all times. There was no loss of tissue except a small area of the outer layer of skin at the lower corner of flap *b* near *e* (Fig. VII). There was no pain on micturition. During the first day after the removal of the catheter, a small amount of urine escaped from a minute fistula at *e* (Fig. VII). This must have closed at once, for the patient was directed to hold a small piece of dry gauze over the opening at each micturition for a few days, and there has been no further escape of urine. There was a slight urethral discharge for four weeks, the abundance of which was not influenced by the use of salol, but it entirely dis-

appeared in a week after the use of oil of sandalwood. The pus cells contained no diplococci, and the discharge was undoubtedly due to small granulating areas along the new urethra, together with a certain amount of catarrhal inflammation of the whole urethral mucous membrane from catheter irritation. There were no subjective or objective symptoms of a posterior urethritis.

It is now eight months since the operation, and the new urethra is perfectly competent in all respects.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

J. G. MUMFORD, M.D., SECRETARY.

REGULAR Meeting, Monday, January 11, 1897, Dr. C. J. BLAKE in the chair.

ANATOMICAL SPECIMENS.

DR. H. H. A. BEACH: This kidney is that of a man of middle age whose symptoms were anemia, debility and loss of flesh without pain. One examination of the urine showed a very slight trace of blood, and that was microscopic in character. The symptoms existed from June to the present time. The growth first appeared in the lumbar region, extended forward, and had been regarded as splenic in character until Dr. Fitz diagnosed renal growth and sent the man to the hospital. The abdominal operation was performed, first ascertaining that another kidney existed. The growth was a large-celled sarcoma, and weighed three pounds. Dr. Whitney makes the following report upon the growth:

A rounded mass, the size of a child's head, weighing about three pounds, involving about one-third of the upper part of the kidney. The capsule of the kidney blended with the fibrous covering of the growth, which was rough, and upon which was several small, rounded, secondary nodules.

The kidney was quite sharply defined from the growth, and microscopic examination showed evidence of connective-tissue increase, with atrophy of the kidney substance close to it. Elsewhere the kidney was pale, but otherwise normal. On section the greater part of the growth was seen to be of a uniform, opaque, yellow color, and the microscopic examination of this part showed simply fatty degenerated cells and detritus. At the edge this tissue was more translucent, pale, and of a medullary aspect, and a distinct lobulation could be seen. Microscopic examination of this part showed it to be made up of large round cells, among which were scattered irregularly-shaped protoplasmic masses, with very large nuclei, three or four times as large as the average cells. The cells seemed to have a little granular intercellular material, and there were no well-formed blood-vessels. Close to where it joined the kidney was a line of tissue of an old-gold color, recalling that of the suprarenal capsule.

The diagnosis is a large, round-cell sarcoma, rapidly growing and undergoing anemic necrosis. It probably originates from the suprarenal capsule, possibly from a misplaced fragment in the kidney.¹

Dr. A. T. CABOT reported a case of

CYST OF THE BRAIN.²

¹ This patient died in the following March of a recurrence of the growth in the brain.

² See page 533 of the Journal.

DR. J. W. ELLIOT reported a similar case.³

DR. J. J. PUTNAM: Dr. Cabot's case is one of the most interesting and satisfactory that we have had at the Massachusetts Hospital. He has alluded to the fact that consciousness was rarely lost in these attacks, even in those which were comparatively severe, and that nitrite of amyl seemed singularly efficient in checking them. In the latter attacks, however, in spite of the slight impairment of consciousness, a considerable degree of paresis of the arm and leg was left behind. It is usually supposed that when impairments of motion of this sort followed epileptic attacks it is a sign of exhaustion attending strong muscular spasm; but it is evident that such is a narrow view. A number of cases are on record where paresis has come on without antecedent convulsion. Féré thinks that some of these cerebral seizures may be considered as analogous to dreams, and that the motor weakness may be analogous to that which sometimes follows dreams.

The failure of electrical excitations to excite responses over this cyst was quite striking, although the yellowish color was sufficient to indicate to a trained eye the fact that there was something abnormal. No contractions could be produced there until the electrode passed beyond the limit of the cyst, although this was covered by a layer of brain tissue. The change in the distribution of the sensory symptoms from the neighborhood of the thigh to the side of the neck and the neighborhood of the ear, and also to the arm, was very striking and interesting, and in that connection I would like to mention the fact that I have noticed in several cases, that the peculiar numbness and prickling which sometimes accompanies hemiplegia was most marked in the neighborhood of the ear. In the cases to which I have alluded the symptoms were certainly referable to the internal capsule, and it strikes me as most probable that this cyst did eventually reach far enough to cause pressure on the motor and sensory fibres of the internal capsule. The impairment of hearing and the hemianopsia was also extremely interesting. At first, the hemianopsia came on only after attacks, but afterwards it became more or less persistent. The disturbance of hearing was associated with a sound more or less like that of a shell over the ear. I have seen several cases in which the two ulnar fingers of one hand seemed to be more affected with sensory symptoms than the other fingers, although one would suppose that the index finger and thumb being most used would be most likely to show sensory as well as motor symptoms. In this case there was no distinct differentiation between the fingers except as the paralysis came on as it did after some of these very slight attacks, at the end of five or ten minutes. Under these circumstances it would affect first the fifth and fourth finger, then the third and second and first in turn.

As early as February, 1894, which was a few months after the first operation, there was more or less ataxia and sensory impairment of the hand and foot.

It would be very interesting if there was time, to discuss the pathology of these cysts, because it is not clear how they occur and how the limiting wall is made. Where the tissue is melting down under the pressure of the fluid it would seem doubtful if there is a distinct wall. As regards Dr. Elliot's patient, I saw him many times in the out-patient department and after he went into the hospital, and the gradual spread of the convulsions from the index finger and thumb to

the rest of the fingers and then to the wrist and arm and shoulder was certainly very striking as illustrating what Dr. Hughlings Jackson has pointed out confirming our ideas of the anatomical arrangement of these different centres with relation to development.

DR. BEACH: I have been much interested in the cases of Drs. Cabot and Elliot, for the late histories, after such operations are of the greatest importance. The analysis of 19 cases recently published by Sachs and Gerster of New York, gives a rather gloomy, outlook excepting those where the symptoms are of recent occurrence. They agree with those who insist "that no case of epilepsy can be said to be cured unless the patient has been entirely free from the attacks for a period of at least a year. . . . Possibly this period should be extended to three years." They criticised a case published by me in 1890, and some reports of Horsley, as having been made too soon after the operations. My case was not reported for ten months after the operation, to provide for the possibility of recurrence of symptoms. Fifteen months after the operation, the patient was thrown down violently by her dress catching upon a wagon step while alighting and struck upon the site of the old operation. Convulsions occurred again, and continued until the operation was repeated in the spring of 1892; and a gold plate was then inserted to prevent a re-adhesion of the brain to the skull and to protect the brain from injury. This case was exhibited to the members of the American Surgical Association visiting Boston at their annual meeting in 1892; but the report of the case has been purposely delayed five years to be as sure as possible of the question of recurrence. My case was cured for fifteen months, and without the *accidental* fall might have had immunity from seizures for an indefinite period. As far as one record can supply evidence, it raises a doubt as to the expediency of establishing a rigid rule for the time when these cases may be considered cured, at least for the present.

DR. E. W. TAYLOR: There are a certain number of points, from the pathological point of view, which have been briefly touched upon, of particular and extreme interest, especially since our knowledge of the neuroglia has of late grown to such an extent. Within the last few years we have arrived at certain methods of staining the neuroglia which have thrown new light upon the subject of the pathology of the brain in general, and particularly upon those conditions of which cyst is a very excellent example. The feeling has been growing rapidly that the part which connective tissue plays in reparative processes in the central nervous system is comparatively insignificant. In processes such as cysts of the brain of this non-congenital sort, we unquestionably have the reparative process consisting almost entirely of a reproduction of neuroglial tissue rather than of connective tissue. The term connective tissue should be dropped except in so far as we have to do with its proliferation in relation to the membranes and blood-vessels.

The first point of practical importance is the question of the cyst wall. According to the present view, such a cyst wall would be made up chiefly of neuroglial tissue, consequently the question suggested by Dr. Putnam, as to whether we have a wall at all is certainly *apropos*. Probably we have simply a proliferation of neuroglia, which is to be regarded as a conservative process on the part of nature to fill up the gap occasioned by a previous destructive process. No

³ See page 536 of the Journal.

doubt it would be possible to take out a good part of this thickened neuroglia, but the idea of removing the wall as a wall, if this view be correct, would be a physical impossibility. Dr. Horsley's suggestion of excising the entire cyst and considerable tissue about the cyst is of interest, since no doubt he has had successful results from such operation. By this procedure we substitute a clean surgical cut for the rough and irregular wall of the original cyst, which possibly is more irritative than the clean cut would be. There would, no doubt, be a certain degree of reparative process on the part of the neuroglia, but not one that would be of the same irritative character as the original wall, if left intact.

The further question comes up as to how such a cyst becomes obliterated. If obliteration occurs, it must, in great measure, be due to a reactive predisposition on the part of the neuroglia. In cysts of considerable size such obliteration probably would not occur or, at best, imperfectly.

Dr. Elliot brought out the interesting fact, that possibly in this case he had a cyst growing in a glioma or a glioma extending from the cyst. It is probable that further investigation will show that the differences between cysts and gliomatous new growths is not a difference in histological structure, but rather in method of development, so that a glioma may prove to be simply a gliosis which has the power of expansive and continuous growth.

The only other point I should like to mention is the fact of the persistent sensory disturbance from an injury occurring apparently in the motor area, being another observation in support of the now generally accepted view that the motor sphere is a sensory area as well.

AMERICAN GYNECOLOGICAL SOCIETY.

TWENTY-SECOND ANNUAL MEETING, WASHINGTON, MAY 4, 5, 6, 1897.

FIRST DAY. — TUESDAY.

THE Address of Welcome was read by DR. A. F. A. KING, of Washington, who expressed the pleasure he felt in greeting the members of the Society, and hoped the meeting of 1897 might constitute a memorable page in the already distinguished history of the organization.

DR. BACHE McEWEEN EMMET, of New York, read a paper entitled,

MULTIPLE MYOMATA IN THE ABDOMINAL CAVITY.

The author described the pathology of that form of myomata formed of unstriped muscular tissue, and advised a study of their genesis in order to prevent their formation. Although supposed to spring from unstriped muscular tissue only, they are occasionally met with elsewhere, and the author reported an unusual case in which seven of these tumors were removed from the pelvic cavity, all of which were found to have omental attachments and no connection whatever with the uterus.

DR. CHARLES P. NOBLE, of Philadelphia, then read a paper entitled,

THE HISTORY AND PRESENT STATUS OF HYSTERECTOMY FOR FIBROID TUMORS OF THE UTERUS.

He traced the history of the operation from the time it was first performed by Kimball in 1853 to the present day, and dwelt upon the important part played by American surgeons in its development. The operation was an outgrowth of ovariectomy as it was first performed in a case of supposed ovarian tumor, and is therefore of American origin. The various methods of treating the stump were described, and the many advances made in the technique of the operation, all originating in this country, were detailed at length. The paper stated that the mortality of fibroid tumors not operated upon is greater than supposed, while that of supra-vaginal amputation is at present five per cent. In total hysterectomy, the mortality is increased by delay in operating. The author urged early operation, because it insures a low mortality, permits the substitution of myomectomy in women of child-bearing age, and conserves the life and health of the patient.

DR. R. STANSBURY SUTTON, of Pittsburgh, was opposed to operating upon every fibroid tumor of the uterus, and would resort to hysterectomy only when the symptoms urgently demanded it.

DR. ARTHUR T. JOHNSTONE, of Cincinnati, was also in favor of conservative treatment, because in many cases the presence of a fibroid gives no trouble. He had seen good results follow removal of the appendages to arrest the growth of a uterine fibroid. In performing hysterectomy, he leaves part of the cervix whenever this is possible.

DR. B. F. BAER, of Philadelphia, said that, although an advocate of conservative treatment in these cases, he thought this often meant the employment of radical measures. An operation which relieves suffering and saves life is a conservative operation. Supra-vaginal amputation of the uterus is indicated in some cases and myomectomy in others. The menopause rarely arrests the growth of these tumors.

DR. A. PALMER DUDLEY, of New York, laid stress upon the importance of a correct diagnosis before determining upon the operation to be performed, and said that no one method is suitable for all cases.

DR. W. T. LUSK, of New York, advised expectant treatment, as many fibroid tumors exist without producing symptoms. In those cases where operation is demanded, he performs myomectomy whenever possible. Supra-vaginal hysterectomy is preferable to the total extirpation on account of the discomfort produced by sinking of the pelvic contents in the latter operation.

DR. J. M. BALDY, of Philadelphia, said that doing what is best for the patient constitutes conservatism. He therefore performs hysterectomy or myomectomy in such cases as demand it, and treats expectantly those in which it is not indicated. Excessive anemia caused by repeated hemorrhages calls for operation. Removal of the appendages to arrest the growth of a fibroid is rarely successful, because of the difficulty in removing all ovarian tissue.

DR. T. A. REAMY, of Cincinnati, was of the opinion that oöphorectomy has a beneficial effect upon these cases if performed in the early stage; later on neither this nor the menopause will arrest the growth of a uterine fibroid. In view of the fact that these tumors often exist without producing symptoms, he is an advocate of conservative treatment, although he is not opposed to hysterectomy when this is indicated. We should be proud of the fact that surgery has reduced the mortality of this operation to five per cent.

DR. BEVERLY McMONAGLE said that an operation which is conservative in a young woman is not conservative in an old woman. Hysterectomy should be performed in the latter case if pain or discomfort is caused by the tumor. It is better to do myomectomy in women in the child-bearing period, in order that this may not be interfered with. Oöphorectomy should not be undertaken for the same reason.

DR. GEORGE J. ENGELMANN, of Boston, was in favor of expectant treatment, because many of these tumors are not dangerous to life and in many cases are harmless. The establishment of the menopause, instead of checking the growth of a uterine fibroid, often causes the condition to become worse.

DR. SETH C. GORDON, of Portland, Me., expressed himself as being most radical in his views on this subject. He removes all fibroid tumors, large and small, because he considers them a menace to the woman's life, and invariably removes the uterus as well as the appendages. If one could be sure that the growth will not recur, myomectomy would be the better operation in young women.

DR. THOMAS ADDIS EMMET, of New York, thought there was no doubt that fibroid tumors which were originally uterine become transplanted elsewhere in some cases, and mentioned a case in which this took place. He was decidedly in favor of conservative treatment, and was especially opposed to hysterectomy. The causation of these tumors should be learned, and treatment directed toward their prevention.

DR. BACHE EMMET, in closing, said fibroid tumors appeared to be due to a diseased condition of the uterus or to a disturbance of the circulation of the organ, and reiterated his opinion that radical measures are indicated only when there are marked symptoms.

DR. NOBLE, in closing, said that his aim had been to make clear the difference between the conservatism which considers the interests of the patient and that which does nothing. The menopause does not check the growth of these tumors, as shown by the fact that twenty-five per cent. of the women he had operated upon had passed this period.

DR. H. J. GARRIGUES, of New York, then read a paper entitled,

SECONDARY OPERATIONS.

The author said that secondary operations often are made necessary by careless and faulty operating, and dwelt upon the importance of leaving no raw peritoneal surfaces in abdominal operations and of gentle handling of the intestines and other organs, in order that no adhesions may subsequently be formed. He also spoke of the necessity of employing strictly aseptic methods. A number of cases were reported.

DR. BACHE MCE. EMMET, of New York, indorsed the views of the author, and called attention to the fact that many patients are subjected to secondary operations because of an error in diagnosis. Infection is often caused by ligatures, and care should be exercised to avoid this.

DR. A. LAPTHORN SMITH, of Montreal, mentioned a case in which secondary laparotomy became necessary on account of intestinal obstruction caused by adhesion of the gut to a raw peritoneal surface.

SECOND DAY. — WEDNESDAY.

DR. ANDREW F. CURRIER, of New York, read a paper entitled

SUGGESTIONS CONCERNING VENTRAL HERNIA RESULTING FROM ABDOMINAL SECTION, AND ITS TREATMENT.

The author was of the opinion that ventral hernia after abdominal section is not always due to bad technique, but to many other causes, for example, non-resisting condition of the tissues, lack of proper protection after operation, hard work, and fat. He described the condition under three headings: (1) simple, (2) multiple, (3) massive. Early operation was advised in all cases without reference to the symptoms. The following method of closing the wound was given: After freshening the edges of the tissues, all superfluous peritoneum and fat being removed, two curved needles, threaded on the ends of a strand of silkworm-gut, are introduced just above the upper angle of the wound from without inward, passing through fascia, muscle and peritoneum, and are then brought out and again inserted from above downward on the opposite side, and this is repeated until the lower angle of the wound is reached, in exactly the same manner as a shoe is laced. One suture twelve inches in length is sufficient if the wound is not more than three inches long; otherwise a second suture should be employed, beginning at the lower angle of the wound and meeting the one from above in the middle of the wound. The skin is then united with a continuous suture of silkworm gut, and a thin strip of gauze is slipped under each suture to protect the skin. The superficial sutures are removed in two weeks, the deep ones two weeks later. The patient should be kept in bed for a few days after removal of the stitches and adhesive straps worn to protect the wound for the next week or two.

DR. J. M. BALDY, of Philadelphia, said he has employed a suture of silk for the peritoneum, a similar one for uniting the fascia, and silkworm-gut for the skin, with good results.

DR. A. LAPTHORN SMITH, of Montreal, spoke of the importance of allowing the sutures to remain in the tissues for a long time. Hernia rarely follows operation if this is done. In closing the wound, he employs silkworm-gut sutures, one-third of an inch apart, taking in peritoneum, fascia and skin. In women with fat abdominal walls, a buried suture which includes peritoneum and fascia is employed, and the rest of the wound closed by another row.

DR. JOSEPH TABER JOHNSON, of Washington, thought that most of the methods advised for closure of the abdominal wound occupy more time than the operation itself, and are therefore undesirable. He employs a through-and-through suture, near together and taking up a good deal of the structures, with very good results.

DR. CHARLES P. NOBLE, of Philadelphia, said that for the past five years he has employed buried sutures of silkworm-gut in closing abdominal wounds, and was convinced that the best results are to be obtained by this method. In 400 cases treated in this manner, suppuration occurred in only 10, and hernia followed in but two cases. The speaker was of the opinion that there would be but few ventral herniae if more time were devoted to closure of the abdominal wound.

DR. A. P. DUDLEY, of New York, said that hernia would not occur if the edges of the linea alba were properly brought together, and he doubted if it were possible to get union by overlapping the fascia, nor

did he approve of any method of suture which united all the structures. To secure a good result it is not only necessary to approximate the different tissues, but they should be held firmly together for some time. He has operated on twelve cases, with very satisfactory results, by the following method: The peritoneum is drawn together with fine catgut; silver-wire sutures are then passed through the muscles and fascia, a small silver canula is then passed over the ends of each suture, and the latter are drawn tight and shouldered as in Emmet's operation for trachelorraphy; no sutures are inserted in the fat and cellular tissue, but between each silver suture the skin is held together with silkworm-gut.

DR. CERRIER, in closing the discussion, said that any method by which the wound could be closed quickly and properly would, indeed, be desirable; but he hardly thought the one advocated in his paper could be said to be complicated. He employs several rows of sutures, for the reason that he does not think it possible to get a good result with a suture which included all the tissues.

The President, DR. JAMES R. CHADWICK, of Boston, then read his Address, which was

AN HISTORICAL SKETCH OF ABDOMINAL SURGERY.¹

DR. THOMAS ADDIS EMMET, of New York, said that the younger members of the Society could have no idea of the opposition offered by the profession to ovariectomy and similar operations when Dr. Sims founded the Woman's Hospital of New York. Surgeons refused to assist, and would not even countenance an operation by seeing a case in consultation, and a man who dared to remove an ovarian tumor was looked upon as a murderer.

DR. EDWARD P. DAVIS, of Philadelphia, read a paper entitled,

PRIMARY TUBERCULOSIS OF THE BREAST COMPLICATING PREGNANCY.

The author said that primary tuberculosis of the breast is a rare condition and that but few cases were found in the literature. He reported a case of a young woman in whom the disease complicated her first pregnancy. The diagnosis was made by microscopical examination of the secretion of the breast and confirmed by the pathologist's report on the tumor when it was removed after delivery. There was no history of injury, no condition of general tuberculosis, and the breast had evidently been infected by the mouth of a tuberculous individual. He also mentioned a case in which a tumor, supposed to be sarcoma, was removed, together with the entire breast, from an unmarried woman, and found to contain multiple tuberculous abscesses. The tumor involved the outer border of the breast and extended into the axilla; the nipple was not affected.

DR. H. T. HANKS, of New York, said he had met with one case of the kind complicating pregnancy. The tumor was diagnosed as cancer of the breast, and the patient was septic when seen. After delivery the breast was amputated; and the woman died three days later of sepsis.

DR. PAUL F. MENDÉ, of New York, read a paper entitled,

PERITYPHLITIS AND APPENDICITIS IN THEIR RELATIONS TO OBSTETRICS AND GYNECOLOGY.

The author said that as it is only within the past ten years that inflammation of the appendix has been recognized, inflammatory conditions of the right iliac and cecal region were formerly termed "perityphilitis." The disease was also supposed to be confined to the male sex, probably because the many inflammatory conditions of the abdomen in women caused the appendix to be overlooked. He reported a number of cases occurring in women and called attention to the following points: (1) the possibility of the occurrence of appendical inflammation, either as a new disease or as a recurrence of a previous attack, at any time during pregnancy, or even during labor and the puerperal state; (2) the induction of abortion or premature labor by the acute appendicitis, either in consequence of the local irritation or through the fatal effect on the ovum of the general hyperpyrexia; (3) the difficulty of diagnosis of the true nature of the case, especially when the pain in the right iliac region is masked by the natural labor pains, or the attacks occur after delivery, and the high temperature may be mistaken for that of puerperal septic infection; (4) the necessity for prompt surgical interference, whether the attack occur during labor or the puerperal state; (5) the danger of a greater mortality, owing to the possible postponement of the operation in consequence of the difficult diagnosis, or to the risk of genital infection.

DR. FORD mentioned a case of a young girl in whom a large quantity of pus was found in the pelvis and evacuated by vaginal incision, a few days after he had operated upon her for appendicular abscess. He also reported a case where death resulted from iodoform poisoning caused by packing the pelvic cavity with iodoformized gauze after evacuating a very large quantity of pus. The girl had a heart lesion and this, perhaps, was a factor in the case.

DR. A. LAPHORN SMITH, of Montreal, had seen a number of cases in which the appendix was found adherent to the right tube.

DR. E. C. DUDLEY, of Chicago, reported a case of a woman in whom four abscesses developed in the right side at intervals of a few weeks. When the fourth appeared, the speaker was asked to see the case. An appendicular abscess was found and the appendix removed. In another case an abscess of the appendix and a ruptured pus-tube were found.

DR. H. T. HANKS, of New York, said that he had met with many cases of appendicitis and disease of the right tube coexisting.

DR. BAKER remarked that in cases where appendicitis and tubal disease both exist, the former is probably the primary condition.

DR. R. A. MURRAY, of New York, read a paper entitled,

THE TREATMENT OF SYPHILITIC WOMEN IN PREGNANCY AND PARTURITION.

The author said that syphilis is the most common cause of premature birth and abortion, and described the changes which take place in the placenta, endometrium and fetus as a result of this disease. Treatment should be directed toward preventing these changes; and the anemia, which is the main factor in causing the death of the fetus, calls for remedies which will increase the hemoglobin in the blood of mother and child. He has found inunction to be a more satisfactory method of administering mercury than giving it

¹ See Journal of May 6, 1897, p. 429.

by mouth, and, after delivery, employs it in the case of the child. He called attention to the fact that in first pregnancies, where the woman's husband is syphilitic, the disease usually appears first in the throat.

DR. EDWARD P. DAVIS, of Philadelphia, was of the opinion that, in order to make a diagnosis in these cases, an examination of the genital tract should be made.

DR. A. PALMER DUDLEY, of New York, read a paper entitled,

SOME PATHOGNOMONIC PHYSICAL SIGNS OF CHRONIC GONORRHEAL INFECTION IN WOMEN AND THEIR VALUE IN DIAGNOSIS OF PELVIC DISEASE.

The following points in differential diagnosis were given: (1) pathological changes within the urethra, attended by pain at neck of bladder and painful micturition; (2) abscess of the vulvo-vaginal gland; (3) chronic senile vaginitis; (4) pernicious leucorrheal discharge from cervix; (5) dysmenorrhea from stricture of internal os; (6) structure changes in endometrium resulting in menorrhagia; (7) pathological changes in Fallopian tubes; (8) the effect of the gonococcus upon the ovary; (9) the different forms of displacement that accompany this condition; (10) sterility.

(To be continued.)

Recent Literature.

An American Text-Book of Physiology. By Henry P. Bowditch, M.D., John G. Curtis, M.D., Henry H. Donaldson, Ph.D., W. H. Howell, Ph.D., M.D., Frederic S. Lee, Ph.D., Warren P. Lombard, M.D., Graham Lusk, Ph.D., W. T. Porter, M.D., Edward T. Reichert, M.D., and Henry Sewall, Ph.D., M.D. Edited by WILLIAM H. HOWELL, Ph.D., M.D., Professor of Physiology in the Johns Hopkins University, Baltimore, Md. Fully illustrated. Philadelphia: W. B. Saunders. 1896.

In this work it has been attempted to give an account, adequate for the purposes of student and practitioner, of the present position of physiology. The method adopted in the preparation of the work has been that of collaboration by ten authors, to each of whom one division of the subject is allotted. The multiplication of writers no doubt permits, as Professor Howell tells us in his preface, of a more perfect mastery by each of the parts of the field to be described by him. It may be regretted, nevertheless, that the adoption of the principle of the division of labor has only resulted in a rather unwieldy students' text-book, for the preparation of which after all a complete command of the whole of current physiology can hardly be regarded as necessary, and not in a *Handbuch* taking the place in the English language of "Hermanu" in the German. From the publisher's point of view, no doubt, the non-attainment of this result is more than compensated for by the probable use of the work by a large number of students, since all the collaborators are well-known teachers of physiology.

Professor Howell has written an admirable general introduction, after which Professor Lombard discusses quite adequately the general physiology of muscle and

nerve, making considerable use of Biedermann's recently published "Electrophysiologie," but at the same time introducing a number of excellent original muscle tracings.

Professor Howell then treats of "Secretion," "The Chemistry of Digestion and Nutrition," "The Movements of the Alimentary Canal, Bladder and Ureter," and "Blood and Lymph." The treatment of all these subjects is excellent, the discussion being very consecutive, clear and complete.

The section on the Circulation is the work of Professors Curtis and Porter. Professor Curtis discusses the mechanical aspect of the circulation of the blood and lymph, while Professor Porter treats the innervation of the heart and blood-vessels and the nutrition of the heart. Both these authors give more references to the literature of their subjects than their collaborators have done. Professor Porter especially has multiplied authorities to an extent which — although most valuable to the advanced worker — may be somewhat embarrassing to the elementary student.

Professor Reichert is responsible for the sections on Respiration and Animal Heat, both of which subjects are adequately treated.

The "Central Nervous System" is the work of Professor Donaldson, and is most excellently done, the latest standpoints being taken in it and all aspects of the subject dealt with.

"The Special Senses" are treated of by Professors Bowditch and Sewall. Professor Bowditch's chapter on Vision is a very good one, the subject being completely and clearly treated. Professor Sewall's account of the other senses is also very well done.

Professors Lombard and Sewall are responsible for the Physiology of the Special Muscular Mechanisms.

Professor Lee has written a very good and up-to-date account of the general physiology of Reproduction.

The section entitled "The Chemistry of the Animal Body" is the work of Prof. Graham Lusk. In it rather a large amount of adventitious matter has been introduced, which hardly belongs to the subject proper, such as very elementary details of inorganic and organic chemistry, and inadequate pharmacological discussions.

Regarded as a whole, it can be said that the book is a success and worthy of its title. The publisher has carried out his share of the undertaking well. A more detailed table of contents and a more careful index would, however, add greatly to the utility of the work.

Genito-Urinary and Venereal Diseases. By WHITE and MARTIN. Philadelphia: J. B. Lippincott Company. 1897.

The need of another work in this department of surgery is questionable. Apart from this, however, the above publication answers very well its purpose, which is stated in the preface to be that of presenting the subjects included in its title in a practical and useful way to both students and practitioners. This end is attained by the clear and concise way in which the book is written, and by the avoidance of discussion of theoretical matters that are *sub judice*.

The portions of the work which seem to us the least well done, are those parts of the first two chapters which deal with the anatomy of the penis and the urethra. These are lacking in illustrations and full-

ness of description. The chapter on the examination of urine is likewise deficient in illustrations; and the pathological significance of certain urinary elements is inadequately presented. The description of the endoscope fails to impress the reader with the importance of its use in chronic inflammations of the urethra.

Among the many good features the following may be noted, as examples: the descriptions of the plastic operations upon the urethra; the chapter upon stricture; the description of syphilis as it affects special organs and tissues, and also the treatment of the disease; the diseases of the prostate; the functional nervous disorders of the sexual organs, and a separate chapter which is devoted to a comparative study of certain symptoms as they occur and vary in connection with different diseases of the urinary organs.

Deutsch's Letters: A Practical Method for Easy and Thorough Self-Instruction in the German Language. By SOLOMON DEUTSCH, A.M., Ph.D. Second and revised edition. New York: J. H. Vail & Co. 1896.

This volume, containing about 500 octavo pages, is a very comprehensive and intelligible text-book for those who wish to study German at their own time and convenience and without the expense of a teacher.

At the start the author makes the encouraging statement that more than half of our common English words are of German origin, and prints lists of some 1,500 German words illustrating the great affinity between the two languages; many of these so closely resemble their English relatives that they are recognized and understood at sight.

Special attention is devoted to pronunciation. In addition to the very full and explicit rules, the correct sound of each word when it first appears in the exercises is accurately indicated. The mysteries of German grammar—with its everlasting declensions, erratic conjugations, and astounding perversities of gender—are also ably elucidated. Colloquial forms of expression are fully exemplified in "conversations" on a great variety of subjects.

A most interesting feature is the "lexicology," a commentary, or analytical explanation of the derivation and meaning of many of the words—often giving one the "reason why," always so welcome to the logical mind.

Typographically the book might be somewhat improved, and a fuller index would add greatly to its value.

Hypnotism and its Application to Practical Medicine.

By OTTO GEORGE WETTERSTRAND, M.D. Authorized translation from the German edition by HENRIK G. PETERSON, M.D. 8vo, pp. xvii, 166. New York and London: G. P. Putnam's Sons. 1897.

The present work was inspired by the teachings of the so-called Nancy school, and it is dedicated to Liébeault. It follows the teachings of that school, to which it adds little that is new except the report of one hundred and twenty-eight cases of different forms of disease treated by suggestion. The translation has been well done, and the translator has added several letters of his own, some of which have already appeared elsewhere, describing the clinique at Nancy and touching upon various matters connected with hypnotism.

THE BOSTON Medical and Surgical Journal.

THURSDAY, JUNE 3, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

A REPORT ON THE LAST EPIDEMIC OF PLAGUE AT HONG KONG.

THE last annual report of the medical officer of health of Hong Kong, published in the *Hong Kong Daily Press* of April 12th, contains some interesting and instructive statistics and observations in regard to the epidemic of bubonic fever or plague which visited Hong Kong in 1896, following the earlier outbreak of 1894 at Canton and in Hong Kong.

The total number of cases of bubonic fever notified during the year, from the second week in January to November 24th, was 1,204, while the number of deaths registered was 1,078; this is equal to a case mortality of 89.5 per cent. The rate of mortality was, however, not constant throughout the epidemic, for among the 342 cases which occurred during the first quarter of the year it was 82.4 per cent., while among the 727 occurring in the second quarter it rose to 94 per cent., and fell again to 77.5 per cent. of the 89 cases occurring in the third and fourth quarters.

Of the 1,204 cases, 804 were males and 390 were females, while in 10 cases the sex was unrecorded; this gives a percentage of 67.4 males and 32.6 females, while the percentages of population are 70.7 males to 29.3 females, so that women, as far as these figures and conditions go, would appear to suffer from the disease to a greater extent than men.

The number of children (under 10 years of age) who contracted the disease was 194, while of the remainder, 974 were adults, and in 36 cases the ages were unrecorded; this shows that 17.5 per cent. of the cases occurred among children under 10 years of age, while the proportion of such children to adults in the colony certainly does not amount to 10 per cent.

Hence the same conclusion results for children.

The disease showed a far greater tendency to spread among Europeans during this outbreak than it did during the greater epidemic of 1894, and no less than 16 Europeans were attacked, 13 being British, 2 Ital-

ians, and 1 Austrian; of these, 8 succumbed, namely, the two Italians and six British — 50 per cent.

In addition to the 16 European cases, there were 28 cases among Indians and 3 among Eurasians, making a total of 47 cases among the non-Chinese community; 31 of these cases died, giving a case mortality of 66 per cent.

Dr. Clark, from whose report we quote, holds that plague is not spread by inoculation through wounds (except in rare cases), but is contracted rather by breathing a foul atmosphere containing the *materies morbi* of the disease (the plague bacillus of Kitasato) which is given off in practically all the secretions and excretions of the patient. This bacillus will retain its vitality in a damp and filth-laden soil, or upon the damp and dirty walls and floors of the dark and ill-ventilated premises in which many of the Chinese of Hong Kong still live, and under favorable climatic or other circumstances will convey the disease to man, and the only measures that will prevent a recurrence of these epidemics, where the disease has gained a footing, are the admission of light and air to the dwellings, the prevention of overcrowding, and the strict enforcement of cleanness, both domestic and municipal.

One of the most characteristic features of the outbreaks of bubonic fever is that the disease almost invariably tends to run its course in some six or seven months, and then to disappear, only to reappear again, however, if the infective material has not in the mean time been destroyed and if the climate happens to be favorable; and this feature of the disease was frequently used, during the past year, as an argument against the necessity for the action taken by the Sanitary Board in cleansing and disinfecting Chinese premises. It was pointed out, and with great truth, that the disease ran a precisely similar course in the city of Canton to that experienced in Hong Kong, and yet no action was taken in Canton to stay the epidemic, while in Hong Kong no less than \$42,000 were spent in combating its ravages; but it must be borne in mind that there are other features of an endemic to be regarded besides its duration, and the most important of these are its extent and the probability of its recurrence. The action taken by the Hong Kong sanitary authorities was founded upon such knowledge as is already possessed by the scientific world of the nature of the disease. Every case of the disease is capable of acting as a centre for the production of other cases and also for the contamination of the soil and buildings in its immediate neighborhood.

The bacilli, moreover, unhappily do not cease to exist at the termination of an epidemic, but remain quiescent in the soil and in other situations, until the next season shall come round which is favorable to their growth. Thus upon the thoroughness of the crusade against these germs will largely depend the probability and the extent of a recurrence of the disease.

Another important means of preventing this dis-

semination of infectious disease which has not been applied in Hong Kong, and to which Dr. Clark calls attention, is, the compulsory disinfection, at regular intervals, of all clothing held by pawnbrokers and second-hand dealers. It is, it seems, a common custom among the coolie class of Chinese to pawn their winter clothing at the termination of the winter season, at the same time redeeming any summer clothing they may have previously pawned. It is a well-established fact, according to this report, that personal clothing and bedding will retain the infection of bubonic fever, as of small-pox and other virulent infectious diseases, for an indefinite period. Hence the systematic disinfection of all such articles by steam is advocated.

Dr. Clark holds that plague almost invariably travels overland, and that there is very little risk of its introduction by shipping, provided that the importation of rags, bedding, and soiled linen is controlled, and that a strict medical inspection of passengers and crew, before they are permitted to land, is enforced. He is not inclined to attach very much importance to the theory that the rats which swarm in vessels carrying grain are responsible for the conveyance of the disease from port to port, either in their own bodies or by contamination of the grain; and he states that the consensus of opinion among the medical authorities in Bombay appears to be entirely against the theory that the disease was introduced into that port from Hong Kong by shipping.

MEDICAL NOTES.

THE CZAR AND THE MEDICAL CONGRESS. — The Czar of Russia has consented to allow his name to be placed at the head of the list of patrons of the Twelfth International Medical Congress.

THE "DIVINE HEALER" STONED. — It is reported that Schrader, the "Divine Healer" was driven out of Clayton, a suburb of St. Louis, by a mob who expressed their appreciation of his services to humanity in the shape of a shower of stones and other missiles.

YELLOW FEVER AT NEW YORK QUARANTINE. — The steamer *Allianca* arrived at New York from Havana, with two cases of yellow fever on board, a waiter and a sailor, who were removed to the quarantine hospital. A passenger had died of yellow fever during the trip. The passengers are detained at quarantine.

MOSQUITO BITE DECIDED TO BE AN ACCIDENT. — The Court of Appeals at Louisville, Ky., according to a report in the daily papers, recently decided a suit against an accident insurance company, brought by Mrs. Sallie Amberg of that city for \$50,000 for the death of her husband, which was caused by a mosquito bite. The lower court held that the bite was not an accident in the meaning of the word as used by in-

insurance companies, but upon appeal Mrs. Amberg got peremptory instructions in her favor.

INTERNATIONAL MEDICAL CONGRESS.—At the meeting of the Section on Laryngeal and Nasal Diseases, the following subjects will be discussed: "Suppurations of the Nasal Accessory Sinuses (except the Maxillary), their Diagnosis and Treatment," by Dr. E. Moure, Bordeaux, and Dr. M. Hajek, Vienna. "Cancer of the Larynx, its Diagnosis and Treatment," by Prof. O. Chiari, Vienna, and Dr. G. Catti, Fiume. "The Causes and Treatment of Loss of Voice in Singers," by Prof. H. Krause, Berlin, and Dr. M. Lermoyez, Paris. "The Progress made in the Treatment of Laryngeal Tuberculosis since the Last International Congress," by Dr. Ruault, Paris, and Dr. J. W. Gleitsman, New York. "Laryngo-Stroboscopy," by Professor Simanowsky, St. Petersburg. "The Use of X-Rays in Laryngo-Rhinology," by Dr. I. Macintyre, Glasgow, and Dr. Mount-Bleyer, New York. "Esophagoscopy," by Prof. V. Hacker, Innsbruck. "The Adoption of Photography to Laryngology," by Dr. I. R. French, Brooklyn, and Dr. Flatau, Berlin. It is proposed in addition to arrange a joint meeting with the other Sections on the question of "Serum Treatment of Diphtheria."

BOSTON AND NEW ENGLAND.

DEATH AT THE AGE OF ONE HUNDRED AND FOUR.—Manuel Oliver Levy, said to be the oldest person in Connecticut, died recently at Stonington, Conn., aged one hundred and four. He was born in Lisbon, Portugal, in 1793. He came to New London, Conn., sixty years ago, and followed the sea during a large part of his life.

PRECAUTIONS AGAINST SMALL-POX.—The Board of Health of Boston have sent out a circular to the physicians of that city requesting especial care in the examination of all cases of chicken-pox, and that they be reported to the board. This precaution is taken owing to the possible danger of a mild case of small-pox (and this is the type of the cases recently discovered in Boston) being mistaken for chicken-pox.

DEATH OF DR. O'LEARY.—Dr. Charles O'Leary died at his home in Providence, R. I., June 1st, of Bright's disease. Dr. O'Leary was formerly president of the Rhode Island Medical Society, and was at one time connected with the faculty of St. Mary's College, Emmetsburg, Md. While there he wrote a Greek grammar that for many years was the standard work in Roman Catholic colleges. He served as surgeon during the Civil War.

THE DANGER FROM BOVINE TUBERCULOSIS.—Dr. W. L. West, of Ellsworth, Me., has reported to Dr. G. H. Bailey that two children of a man named Luther Bridges have recently died of tuberculosis due to drinking milk from a cow which was found when killed to be the subject of extensive tubercular disease, largely localized in the udder. Five of Bridges' nine children are suffering from pulmonary tuberculosis, and several are now, according to the report, fatally ill.

NEW YORK.

FAILURE OF NEW YORK COUNTY MEDICAL SOCIETY'S BILL FOR THE PREVENTION OF THE ABUSE OF MEDICAL CHARITIES.—The meeting of the Medical Society of the County of New York, on May 24th, when the Committee on Abuses of Medical Charity presented its report, was one of the largest in the history of the Society. In the discussion on the report it was claimed that very large amounts were received by certain charitable institutions which charged one dollar a month for treatment of patients and by others from the sale of medicines prescribed by the physicians in attendance. Late in the evening the committee which had been sent to Albany to endeavor to induce the Governor to sign the bill referred to in the report, which had been passed by the Legislature at its recent session, arrived and reported the failure of their mission. Governor Black, they stated, showed in the interview which they had with him some animus against the State Board of Charities, and objected to giving it too much power. The opinion was expressed by one of the speakers at the meeting, Dr. Grandin, that the failure of the bill was due to the hostile influence of the powerful boards of managers of some of the dispensaries and hospitals.

THE NEW YORK STATE MEDICAL ASSOCIATION.—The thirteenth annual meeting of the Fifth District Branch of the New York State Medical Association was held in Brooklyn on May 25th, with the President, Dr. Charles Phelps, of New York, in the chair. The scientific session was opened by a paper by Dr. L. A. W. Alleman, of Brooklyn, on "The Treatment of Convergent Strabismus in Children," in which the subject was treated with special reference to the affection as seen by the general practitioner, and a general discussion followed.

Miscellany.

RECIPROCITY IN MEDICAL LICENSURE.

DR. WILLIAM WARREN POTTER, of Buffalo, President of the National Confederation of State Medical Examining and Licensing Boards, chose this for the subject of his annual address at the seventh annual meeting of that body held at Philadelphia, May 31, 1897. He first paid tribute to the memory of Dr. Perry H. Millard, of St. Paul, then in an introduction reviewed some of the essential points of progress that had been made in State control of medical practice, and finally considered his subject.

THE PROBLEM.—The most important question now to be discussed pertains to the inter-State exchange of licenses, and every friend of State control is interested in establishing this principle. It is one of the objects this confederation is laboring to accomplish, but a most difficult problem for solution. A national registration bureau is desirable, where legally qualified and reputable physicians may be recorded—physicians whose names appear on this register to be

allowed to pass from State to State in the enjoyment of all privileges pertaining to the practice of medicine. Those chiefly agitating the question of reciprocity, however, are specialists who desire to spend profitable vacations at summer resorts, and do not relish the idea of taking State examinations in the localities chosen for their holiday practice. Another class of men, compelled by circumstances to change residence, is more deserving of sympathy; they take the examinations uncomplainingly. Shall a State require of its own citizens a compliance with its practice laws while granting to thrifty summer specialists exemption from their operation? As the State laws forbid discrimination against the inhabitants of each, there is both a legal and a moral bar to such exemptions.

OBSTACLES TO RECIPROCITY.—Equality of standards for admission to the study and practice of medicine is the only enduring basis on which reciprocity can be established. When the several States adopt a uniform level of preliminaries; a uniform period of collegiate training, including uniformity of methods of teaching; and finally, an absolute similarity in the methods of conducting State examinations and granting licenses, then reciprocity will be equitably and permanently established. It is important for the State medical examiners to come to an agreement on these several points, that they may act with intelligence on a common platform. The State imposes a post-graduate examination, and none should be admitted to it who are not holders of diplomas legally obtained from registered and recognized colleges. It is understood, of course, that there must be established a uniform system of recognizing and registering medical schools in the several States.

THE SOLUTION; LEGISLATIVE ENACTMENTS.—The remedies lie in legislative enactments. Those who most loudly and persistently demand inter-State indorsement aim their criticisms at examining boards; whereas these have nothing to do with the question. The statutes in States that have established licensure prohibit inter-State exchange except between such as have equality of standards. The demands of the restless and migratory doctors must be taken to the State legislative halls. Meanwhile, the members of this confederation may assist in bringing the matter to a more speedy conclusion by acquainting their legislatures with the difficulties to be overcome, and by urgently recommending the adoption of such amendments to existing laws as will meet and remove the present defects. Great care must be exercised, however, in the preparation of amendments. The State laws are for the public weal, reciprocity is only for the few. Amendments to existing statutes should be proposed only through State medical examining boards or State medical societies; they are familiar with defects and best know the remedies needed. When legislatures can be persuaded to turn a deaf ear to all amendments that are proposed outside of official sources, it will be a happy day for the friends of State license. The object of this discussion is to divert further criticism of the delay of reciprocity into the proper channel. If legislators could be made to appreciate the fact that public health interests are involved in the question of State license; that every attempt to weaken the principle is a blow at public sanitation; and that higher standards of medical education mean better health for the people, then perhaps it would be easier to obtain and maintain the necessary laws to protect the com-

monwealths against that kind of ignorance, superstition, or super-refinement that always lurks in the environment of quackery.

THE SEMI-CENTENNIAL OF THE AMERICAN MEDICAL ASSOCIATION.

It is fitting that the meeting that will mark the entrance of the Association upon the fiftieth year of its existence should be held in Philadelphia, the city in which it was organized. Next week Philadelphia may be expected to assume the appearance of its old supremacy in medical matters. This it is safe to predict from the labors of the committee of arrangements. The occasion is one to call forth enthusiasm, of which there is seldom any lack at the Association's meetings, but our Philadelphia friends will see to it that that sentiment is not allowed to smother the legitimate work of the meeting. An excellent programme has been arranged, and it will be carried out so far as the time available will permit. In particular, Dr. Senn's presidential address, it may be taken for granted, will be well worthy of close attention. The same may be said of Dr. Davis's address, which is to include an account of the origin of the Association and something of its history. Dr. Roberts, the chairman of the committee on anniversary exercises, expresses the hope that the few other surviving original members besides Dr. Davis—namely, Dr. Stillé, of Philadelphia, Dr. Johnson, of St. Louis, and Dr. Atwater, of Springfield, Mass., will all be present to take part in the meeting—a hope in which every member of the profession should join heartily.

The presence of the presidents of State medical societies and of State boards of medical examiners, who are expected to escort Dr. Davis, "the father of the Association," to the platform, will also, it may well be supposed, lend dignity and solemnity to the spectacle. All things considered, there can be no doubt, we think, that the meeting will be worthy of the occasion, and nobody, we feel sure, will question the wisdom of two successive meetings having been held in the East. —*New York Medical Journal.*

THE RESPIRATORY FORM OF PLAGUE.

THE recent death of Dr. Manser, senior physician to the native hospital in Bombay, which was noticed in our issue of January 21st, has attracted attention to certain forms of the disease which, as the *Medical Press and Circular* remarks, are apt to be overlooked amid the devastations of an epidemic.

Dr. Manser, according to our contemporary, died of pneumonia. "He exhibited none of the ordinary signs of bubonic plague, but a bacteriological examination proved beyond a doubt that his death was caused by the specific organism of the disorder in question. A similar result was obtained in three other cases where hospital patients were reported to have died from pneumonia. In view of these facts, the mortality returns of all places where plague has been epidemic will have to be read by the statistician in a fresh light. In Bombay, for instance, there has been of late an enormous increase in the official list of deaths published under the heading of 'respiratory diseases.' It may fairly be assumed that a proportion of such cases, although diagnosed as pneumonia, fever, or

bronchitis, were really due to bubonic plague of an atypical or ambulant form. The danger of non-recognition of so virulent and eminently contagious a disease is sufficiently obvious to require no more than passing mention. The fact of such an occurrence has long been known to medical writers upon the subject, but it may be doubted if it has gained anything like wide recognition. The reason for this local manifestation offers a problem of great interest and importance to the scientific medical investigator."

Obituary.

DR. BENJAMIN EDDY COTTING.

LIKE those autumn fruits that the frost overtakes, our friend lingered long on the bough, to drop at last silently, but not without leaving pleasant remembrance behind. Experience was his; the experience which lingers in its past, but does not advance in the present. In youth habit graves *sillons*, as of wax, in the brain; in age they become grooves of bronze. He was a vanishing type, but a sturdy example of what created our country and our profession.

Before all he was a doctor. Making his profession his ideal, he identified himself with our Medical Society, of which he was one of the fathers, and with this *JOURNAL*, which he was largely the means of rescuing from decay, and restoring to a front rank. He was devoted to his humbler patients, and his charity was abused. For many years he carried on a large and laborious practice with success. Diffident as to the effects of drugs, he studied more closely the natural history of disease; he guided the helm, rather than sought to force results by active treatment.

Sensitive, and somewhat controversial, he never outlived the belief that a physician owns a family, and that he must own them alone to have their confidence and care for their health. Hence he was among the most punctilious in medical etiquette; and what he rendered to others he expected of them in return.

He was a good diagnostician, and also had a gift in mechanics. He could invent, adapt and apply. He devised some improvements in surgery, and numerous ingenious apparatus.

Tenacious of his own views, if over-convinced, he remained unconvinced. He believed in the constancy of natural laws, and he argued that what had been, would be again. Such views are well illustrated in his writings of "Nature in Disease," and on "Disease as Part of the Plan of Creation." He was, as to drugs, a therapeutic nihilist; but in hygiene and care, he contended that doctors would still be needed were there no drugs. He early embraced the views of Sir John Forbes and Dr. Jacob Bigelow on the self-limited nature of disease; and he carried those views farther than their authors. A sceptic by disposition, he was yet a practical Christian, carrying out the tenets of brotherly love, even against the dictates of his reason. Faith was small, Charity great.

There was another side to his mind than the medical one; and that was as a lover of science. The companion and friend of Jeffries Wyman and of Agassiz, he was broadened by this contact. In the American Academy, and in the Lowell Institute, the vivifying light of the sciences illumined him. In Brazil, he worshipped the great forces of nature; and in Greece he reviewed and profited by the classic past.

Bright, witty, keen, social, he was the epitome of the charming host. Liberal, too liberal in gifts, he was restrained from no good act by a false economy. He gives us a lesson from the past; and he illustrates many fleeting or forgotten virtues.

Born in West Cambridge in 1812, he entered Harvard College in 1830, without conditions. He graduated with honors in 1834, having taken part in two exhibitions and

having been made a member of the Phi Beta Kappa Society.

In 1835-36, he attended medical lectures. In 1836-37, he was medical attendant, or student, at the House of Industry, South Boston.

In 1837, he received his medical degree, joined the Massachusetts Medical Society, and was made librarian of the Medical School. He began practice in Boston.

In 1843, he moved to Roxbury, by the advice of Drs. Hayward and Perry. He was given medical charge of the Lead Works and of the Roxbury Dispensary. He was for eight years physician of the Almshouse. During this time an epidemic of typhus fever brought him 307 cases in one year.

In 1842, he was made President of the Boylston Medical Society, and assisted in reviving it.

In 1845, he was chosen in the American Academy.

In 1861, he united with others in forming the Obstetrical Society of Boston.

In 1868, he was appointed on the Consulting Board of the Boston City Hospital and retained this office until he died.

In 1843, he became Curator of the Lowell Institute and remained until 1897.

There were two marked events in Dr. Cotting's career which had great influence on our profession in the whole State. The first was the reorganization of the Massachusetts Medical Society in 1870, and afterwards, covering the period of his vice-presidency and his presidency.

He was actively opposed to those who professed any exclusive dogma in medicine, and he was equally unfavorable to the admission of women to the State society. His broad views of rational medicine were necessarily antagonistic to the elusive theories of homeopathy; and he, with many older Fellows, feared that the admission of women would weaken the scientific interest of others in the medical meetings. The Massachusetts Medical Society was to Dr. Cotting his life, and almost his religion. He gave his whole soul to its interests, and he was truly the Father of our Society.

The second event was the securing of the financial, and hence the critical independence of the *Boston Medical and Surgical Journal*.

No one who surveys the solid and harmonious ranks of the high 2,000 members of the Massachusetts Medical Society to-day can doubt its value and its professional status. Nor can any one dispute that our medical mouth-piece, the *Boston Medical and Surgical Journal*, is now a worthy exponent of professional opinion. Let it not be forgotten by the present generation how much we owe to him in these two respects.

Of his services as Curator in the Lowell Courses, let others speak, as they have already done. It is enough for his medical biographer to acknowledge the great debt which we owe him for his steadfast and unselfish interest in his and our profession.

After some years of travels and honors, he settled into a serene old age; always retaining his interests in his brethren, his later days were full of wise counsel and profitable interviews. Nature dealt not unkindly with him at last, and a brief illness, alleviated by opiates, terminated in a coma which closed the scene, at fourscore and four years.

An epitome of dates, events and honors follows.

MASSACHUSETTS MEDICAL SOCIETY.

1837. Member Massachusetts Medical Society.

1852. Assisted in forming Norfolk District Medical Society, and gave the Annual Addresses in 1852 and 1872.

1855-57. Recording Secretary of Massachusetts Medical Society. 1837-64. Corresponding Secretary of Massachusetts Medical Society.

1865. Annual Discourse on "Nature in Disease."

1870. Called by President Fisk to help regenerate the Society.

1872-74. Vice-President.

1874-76. President, and instituted annual visits to the District Societies.

Edited the By-laws, and added a By-law creating a Committee on Ethics.

Wrote a Code of Ethics.

Councillor for a long period.
Chairman of Committee on Publications until the end of his life.

BOSTON MEDICAL AND SURGICAL JOURNAL.

1873. In June determined, with Dr. F. W. Draper, to revive and reorganize the *Boston Medical and Surgical Journal*. Edited the JOURNAL five months.
1874. With five friends bought the JOURNAL, and put it on its present foundation.

GIFTS.

Two prizes for medical essays to members of the Massachusetts Medical Society.
An endowment to provide lunches for the Councillors.
A like sum to assist poor students in the Medical School.
A contribution to the printing fund of the American Academy.
To his native town an endowment for a reference library for its high school.

He was one of six physicians who purchased this JOURNAL and shared in its management.

All these sums were given during a long professional life; and his private charities were, for his means, equally liberal.

TITLES.

A.B., A.M., M.D., Harvard. President of the Massachusetts Medical Society. Consulting Physician and Surgeon of the Boston City Hospital. Member of the Obstetrical Society of Boston. Honorary Member of the Connecticut Medical Society. Associate Member of Society for Medical Improvement. Corresponding Member of the Royal Medical Society of Athens, Greece, and of the Academia dei Quiriti at Rome, Italy. Fellow of the American Academy of Arts and Sciences, etc.

Obituary.

JAMES DUNLAP, M.D.

RESOLUTIONS BY THE HAMPSHIRE DISTRICT MEDICAL SOCIETY.

DIED, on the third day of August, 1896, at the Dickinson Hospital in Northampton, Dr. James Dunlap, the oldest physician in this city, and one of the oldest in Hampshire District Medical Society, of which he had been a member since 1852.

Born in Pelham in 1819, he achieved the means of his education by working on farms in summer, and teaching district school in winter. He entered Williston Seminary in 1842, and Amherst College in 1843, thence going to the office of Drs. Daniel and James Thompson for the study of medicine, and from there to the College of Physicians and Surgeons in New York City. He opened an office for practice in Northampton in company with the late Dr. Peck in 1850, there continuing all his professional life — and all his life was professional.

He was greatly devoted to the interests of his profession, and of this Medical Society in which he held from time to time each office, from secretary to president.

Simple and abstemious in his habits, with little taste for amusements, his whole time and life was devoted to the service of those who called upon him and relied upon him for professional aid and counsel, and the number of these was great, he having had for many years as large a practice as any physician in the county. Who among us had not come to esteem the character of Dr. Dunlap for its intrinsic worth? He was punctual, calm, deliberate, cautious, but independent in opinion, kind, upright, and courteous, above reproach or suspicion in his treatment of his medical brethren, a true gentleman of the old school, in which integrity, urbanity, and the qualities which went to make up the old-time family physician, meant much in the past, and mean as much to the profession to-day. Times may change, and conditions change, but the memory of the family physician of days gone by should be perpetuated. Therefore

Resolved, That we place upon the records of this Society, in terms of unqualified praise, our appreciation of the life and character of our late brother, and recommend to members of to-day and hereafter, emulation of the example which he set before us, of professional devotion, as well as of friendship, morality and brotherly love.

J. A. Houston, M.D., Secretary.

METEOROLOGICAL RECORD

Deaths reported 3,043; under five years of age 969; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, diarrheal diseases and fever) 371, acute lung diseases 413, consumption 377, diphtheria and croup 129, diarrheal diseases 62, cerebro-spinal meningitis 41, typhoid fever 35, scarlet fever 35, measles 28, whooping-cough 21, erysipelas 11, malarial fever 8, small-pox (St. Louis) 1.

From typhoid fever Philadelphia 11, New York 6, Cincinnati, Cleveland and Washington 3 each, Chicago and Boston 2 each, Brooklyn 1. From scarlet fever Philadelphia 13, Brooklyn 8, New York 5, Chicago 3, Baltimore and Boston 2 each, Hyde Park and Clinton 1 each. From measles New York 12, Brooklyn 5, Chicago, Philadelphia and Cincinnati 3 each, Cleveland 1. From whooping-cough New York 3, Philadelphia, Brooklyn, St. Louis, Baltimore, Boston and Lowell 2 each, Providence,

Cambridge, Springfield and Brockton 1 each. From erysipelas New York 4, Philadelphia 2, Chicago, Boston, New Bedford, Springfield and Haverhill 1 each. From malarial fever New York 5, Brooklyn 3.

In the thirty-three greater towns of England and Wales with an estimated population of 10,982,524, for the week ending May 15th, the death-rate was 16.5. Deaths reported 3,469; acute diseases of the respiratory organs (London) 198, whooping-cough 102, measles 96, diphtheria 56, scarlet fever 32, diarrhea 32, fever 22.

The death-rates ranged from 10.4 in Swansea to 23.0 in Salford; Birmingham 16.1, Bradford 16.2, Cardiff 13.5, Gateshead 14.4, Hull 15.3, Leeds 13.5, Leicester 12.0, Liverpool 21.2, London 15.6, Manchester 22.3, Newcastle-on-Tyne 19.9, Nottingham 15.2, Sheffield 21.0.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 22, 1897, TO MAY 28, 1897.

Leave of absence for three months, to take effect on or about June 1, 1897, is granted CAPTAIN CHAMPE C. McCULLOCH, JR., assistant surgeon, Army and Navy General Hospital, Hot Springs, Ark.

Leave of absence for one month is granted FIRST-LIEUT. WILLIAM F. LEWIS, assistant surgeon, Fort Apache, Ariz.

Leave of absence for three months, to take effect on or about June 15, 1897, is granted MAJOR EDWIN F. GARDNER, surgeon, Fort Grant, Ariz.

CAPTAIN ISAAC P. WARE, assistant surgeon, is relieved from duty at Madison Barracks, N. Y., and ordered to Fort Grant, Ariz., for duty.

Leave of absence for one month, to take effect on or about June 24, 1897, is granted MAJOR HENRY McELDERRY, surgeon, Fort Leavenworth, Kan.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE WEEK ENDING MAY 22, 1897.

BAILHACHE, P. H., surgeon. Detailed to represent Service at meetings of the American Medical Association to be held in Philadelphia, Pa., June 1 to 4, 1897. May 20, 1897.

STONER, G. W., surgeon. Detailed to attend meetings of American Medical Association. May 20, 1897.

IRWIN, FAIRFAX, surgeon. Detailed to attend meetings of American Medical Association. May 20, 1897.

PROCHAZKA, EMIL, assistant surgeon. When relieved at Reedy Island Quarantine on or about May 28th to report at Bureau for physical examination. May 20, 1897.

THOMAS A. R., assistant surgeon. To proceed from Boston, Mass., to Reedy Island Quarantine for duty, to arrive there on May 28, 1897.

GREENE, J. B., assistant surgeon. To proceed on May 23d from Detroit, Mich., to Evansville, Ind., for temporary duty. May 18, 1897.

GRUBBS, S. B., assistant surgeon. To report to medical officer in command, New York, N. Y., for temporary duty May 18, 1897. To proceed from New York, N. Y., to Detroit, Mich., for temporary duty. May 22, 1897.

APPOINTMENT.

SAMUEL B. GRUBBS, of New York, commissioned as assistant surgeon. May 17, 1897.

SOCIETY NOTICE.

MASSACHUSETTS MEDICO-LEGAL SOCIETY.—The annual meeting will be held at the Medical Library, 19 Boylston Place, on Tuesday, June 8th, at 12 M.

Dr. W. F. Whitney will read a paper entitled, "Specimens preserved with their Natural Colors by Kaiserling's Method."

Dr. E. P. Hurd will read a paper entitled, "Sudden Death due to Alcoholism."

Dr. William D. Swan will read a paper entitled, "Gunshot Wound of the Head."

Members of the medical profession are cordially invited.

JULIAN A. MEAD, M.D., Secretary.

RECENT DEATH.

ASA FLANDERS PATTEE, M.D., M.M.S.S., died in Boston, May 31, 1897, aged sixty-two years.

BOOKS AND PAMPHLETS RECEIVED.

Annual Report of the Managers and Officers of the State Hospitals of New Jersey for the Year ending October 31, 1896.

The Therapeutic Value of Hydrobromate of Scopolamine in Plastic Iritis. By Charles A. Oliver, A.M., M.D., Philadelphia. Reprint. 1896.

Warner's Pocket Medical Dictionary of To-day, Comprising Pronunciation and Definition of 10,000 Essential Words and Terms Used in Medicine and Associated Sciences. By William R. Warner. Philadelphia: William R. Warner & Co. 1897.

Clinical Lessons on Nervous Diseases. By S. Weir Mitchell, M.D., LL.D. Edin., Member of the National Academy of Sciences; Honorary Fellow of the Royal Medico-Chirurgical Society of London. Philadelphia and New York: Lea Brothers & Co. 1897.

Twentieth-Century Practice; An International Encyclopedia of Modern Medical Science. By leading authorities of Europe and America. Edited by Thomas L. Stedman, M.D., New York City. In twenty volumes. Vol. IX. Diseases of the Digestive Organs. New York: William Wood & Co. 1897.

Contribution to Traumatic Abdominal Surgery. I. Report of a Case of Contusion and Subsequent Gangrene of a Portion of the Ileum, Complicated by Laceration of a Horseshoe Kidney. II. Report of a Case of Gangrenous Strangulated Hernia. By Thomas H. Manley, M.D., New York. Reprint. 1897.

A Contribution to the History of the Respiration of Man, being the Croonian Lectures delivered before the Royal College of Physicians in 1895; with Supplementary Considerations of the Methods of Inquiry and Analytical Results. By William Marcet, M.D., F.R.C.P., F.R.S. London: J. & A. Churchill. 1897.

Lectures on the Treatment of Fibroid Tumors of the Uterus, Medical, Electrical and Surgical. By Franklin H. Martin, M.D., Professor of Gynecology, Post-Graduate Medical School of Chicago; Surgeon, Woman's Hospital of Chicago, etc., Author of "Electricity in Obstetrics and Gynecology." Chicago: The W. T. Keener Co. 1897.

Diseases of the Ear, Nose and Throat and their Accessory Cavities; a Condensed Text-Book. By Seth Scott Bishop, M.D., LL.D., Professor in the Chicago Post-Graduate Medical School and Hospital; Surgeon to the Illinois Charitable Eye and Ear Infirmary, etc. Illustrated with 100 colored lithographs and 168 additional illustrations. Philadelphia, New York, Chicago: The F. A. Davis Co. 1897.

Retinoscopy (or Shadow Test) in the Determination of Refraction at One Metre Distance, with the Plane Mirror. By James Thorington, M.D., Adjunct Professor of Diseases of the Eye in the Philadelphia Polyclinic, and College for Graduates in Medicine; Ophthalmologist to the Vineland Training School for Feeble-Minded Children, etc. Twenty-four illustrations. Philadelphia: P. Blakiston, Son & Co. 1897.

Syngomyelia, An Essay to which was awarded the Alvarenga Prize of the College of Physicians of Philadelphia for the Year 1897. By Guy Hinsdale, A.M., M.D., Fellow of the College of Physicians of Philadelphia and of the American Academy of Medicine; Member of the American Neurological Association; Assistant Physician to the Orthopedic Hospital and Infirmary for Nervous Diseases, etc. Philadelphia: P. Blakiston, Son & Co. 1897.

Diseases of the Eye and Ophthalmoscopy; a Handbook for Physicians and Students. By Dr. H. Eugene Fick, University of Zürich. Authorized translation by Albert B. Hale, A.B., M.D., one of the Ophthalmic Surgeons to the United Hebrew Charities; Consulting Ophthalmic Surgeon to Charity Hospital, Chicago, etc. With a glossary and 158 illustrations, many of which are printed in colors. Philadelphia: P. Blakiston, Son & Co. 1896.

A Clinical, Pathological and Experimental Study of Fracture of the Lower End of the Radius, with Displacement of the Carpal Fragment toward the Flexor or Anterior Surface of the Wrist. By John B. Roberts, A.M., M.D., Professor of Anatomy and Surgery in the Philadelphia Polyclinic; Professor of Surgery in the Woman's Medical College of Pennsylvania; Surgeon to the Methodist and Jewish Hospitals. With 33 illustrations. Philadelphia: P. Blakiston, Son & Co. 1897.

International Clinics: A Quarterly of Clinical Lectures on Medicine, Neurology, Surgery, Gynecology, Obstetrics, Ophthalmology, Laryngology, Pharyngology, Rhinology, Otology and Dermatology, and specially prepared Articles on Treatment. By Professors and Lecturers in the leading Medical Colleges of the United States, Germany, Austria, France, Great Britain and Canada. Edited by Judson Daland, M.D. (Univ. of Penn.), Philadelphia, Instructor in Clinical Medicine and Lecturer on Physical Diagnosis in the University of Pennsylvania, etc., J. Mitchell Bruce, M.D., F.R.C.P., London, England, Physician to and Lecturer on the Principles and Practice of Medicine in the Charing Cross Hospital, etc., David W. Finlay, M.D., F.R.C.P., Aberdeen, Scotland, Professor of Practice of Medicine in the University of Aberdeen. Volume I. Seventh series, 1897. Philadelphia: J. B. Lippincott Co. 1897.

Address.

AN EPOCH IN MEDICINE IN AN AGE OF DELUSION.¹

BY ZABDIEL BOYLSTON ADAMS, M.D., FRAMINGHAM, MASS.

Quis deus hanc, musæ, quis nobis extudit artem?
Unde nova ingressus hominum experientia cepit?

MR. PRESIDENT AND FELLOWS OF THE MASSACHUSETTS MEDICAL SOCIETY. — He is to be accounted most happy who can find the fitting word to speak before this Society to-day, for we have reached, as I conceive, the grandest epoch in the history of medicine; an epoch in which Massachusetts physicians have borne a conspicuous part.

A review of the history of medicine in modern times calls to mind an exclamation of that famous Scotchman, John Hunter: "Of a' things upon the face of the airth a definition is the most carsed." He was addressing his students, it is said, at St. George's Hospital in the city of London more than a century ago. His sane, downright, Scotch spirit was in revolt against a supremacy of words in our science over all the facts of experience and observation.

Nevertheless, it seems a proper and a cheerful thing to offer a definition at the beginning of an address.

Let me, therefore, say, that by the science and art of medicine is meant the science and art of healing the sick. But this definition, as usually construed, deserves all the condemnation which John Hunter bestowed upon its kind; and I shall ask you to taste a "bitters" of the very wormwood and quassia of error and self-deception, but so sweetened and tintured with pleasant condiments, I hope, as to send you to our annual dinner with sharpened appetites and stomachs in good humor.

We would fain believe that credulity and ignorance played upon by dishonesty and deception make up the sum of quackery. This is a mistake.

It is a familiar fact in the history of medicine that in all ages, as well in times of greatest enlightenment and civilization as in those of darkness and barbarism, have been found men accounted wise, with full faith in the healing virtues of charms and amulets, of the magic of a king's touch, of sympathetic powders or salves that were rubbed upon the weapon, of panaceas such as tar-water, of Perkin's tractors, etc. And in this our day, when we look with pride upon the wonderful advances which our profession has made in the century now closing, we see all about us men of wisdom and influence — trusted financiers, great inventors, philosophers, scientists, preachers — who in their time of sickness do not hesitate to use proprietary or secret remedies of which they know nothing, to consult ignorant charlatans and quacks, or perhaps apply to Spiritualism or Christian Science; and even instructed physicians, who declare a belief in the specific virtues of the attenuation of echoes of the explosion of alchemy,² or like miraculous products of a pharmacy of words.

So appalling seems the mystery of life and death, so strange and inexplicable the phenomena of health

and disease, that it is no wonder that superstition has hovered over them and taken these things to its peculiar care. The subtle influence of the passions and emotions, the imagination and even of the will, over the nutrition of our bodies, has all the charm of magic and the supernatural.

Astrology, alchemy, medicine, appear closely associated through all the ages, working for the advantage of humanity; the first, studying the heavens to cast the horoscope of man and reveal his destiny; the second, compounding the elements to bring forth the philosopher's stone to give riches and eternal youth to man; the third, seeking for medicines of the earth to heal his diseases. Medicine has claimed to hold a more exalted position than the others as having dominion over life and death. Alas! not even the revelations of the microscope, "that telescope of the inner firmament," as Dr. Holmes has called it, have been able thus far to justify the claim. Astrology slunk away like a ghost before the dawn of astronomy. Alchemy was exploded, and we have chemistry. But medicine has long wandered groping, enveloped in the fogs and darkness of theories, or stumbling in the quagmires of systems.

All the so-called systems of medicines since the time of Hippocrates have been mere subtleties of the human mind, hypotheses, dogmas, words. These systems have taken a great variety of forms, which resolve themselves mainly under two classes, the material and the spiritual, matter and mind; and medical science may be typified as a huge snake going round and round through the cycle of the ages trying to seize its two tails of many hues, now one and now the other, or frequently both together, as in the spiritual theory and chemical practice of the pseudonym charlatan Bombastes Paracelsus, or in the attempt of Hoffman, of Leyden, to reconcile the material and the spiritual views, or of Cullen, in Scotland, with his "solidism" and "spirituality." Even up to the present time the unhappy snake seems to be trying to swallow himself, finds that he disagrees with himself, and only makes healthy growth in the accumulation of facts and observations. The perennial Goliath of theory has been slain over and over again by the one little stone of fact; the hydra-heads of system have been stricken off, one after another, by the Hercules, Common Sense.

The art of medicine, or of healing the sick, seems to be indissolubly associated in the minds of men with the use of drugs or physic of some sort. The physician is the dispenser of physic. There is a universal feeling that you must take something if you are sick. "You are ill, what are you taking?" is the inevitable question. Now, if we have not learned it by experience, we have been told often enough by our most learned teachers and practised professors, Bigelow, Holmes, Cotting, in this Society, as well as by others of great renown in England and Europe, that there is no such thing as a specific, and that diseases are not cured by drugs. This may not be absolutely true, but it points to a grave defect in our definition of medicine as the "art of healing the sick."

The very protoplasm of quackery, so to speak, exists in the faith in specifics, in systems based upon

¹ The annual discourse delivered at the Annual Meeting of the Massachusetts Medical Society, June 9, 1897.

² A very intelligent homeopath told the writer that the three-hundredth dilution of "natron muriaticum" was a specific for malarial fever.

³ "Astrology, alchemy, the once general belief in the healing effect of the royal touch, are only various exhibitions of one superstition, having for their essence the same little grain of truth, and for the outward expression different forms of error." — A Book about Doctors, by T. Cordy Jeallreson.

the effect of drugs. The fallacy of the evidence, that is, the so-called "facts of experience and observation," is abundantly shown in the recommendations and certificates of quack medicines. It has been wittily said that to bring forward a hundred cases successfully under the use of some remedy or system "should have no more effect than showing so many fat people in proof of a good government."

In that musty thesaurus of worm-eaten quotations, "The Anatomy of Melancholy," are many passages from forgotten authors showing contempt for doctors and their drugs; "but," says the author, "I will urge these cavilling and contumelious arguments no further, lest some physician should mistake me and deny me physic when I am sick; for my part I am well persuaded of physic. I can distinguish the abuse from the use. I acknowledge it a most noble and divine science. 'The Lord hath created medicines of the earth and he that is wise will not abhor them,' saith Ecclesiasticus."

Now is not this attitude of mind of Robert Burton seen to be similar to that of many of the wisest of mankind, physicians or not?

But there is something still more to my purpose in this unique book. Burton enumerates some fifty or more drugs and simples in which he has faith, including a few which he deems indispensable to the armamentarium of the physician. To-day scarcely one of them is believed to have any special value, or is thought worthy of mention in our pharmacopœias. If the medicines approved by this sagacious, philosophic and erudite author have not borne the test of time, what grounds have we to expect that other and newer remedies may have a more enduring success?

So that we are led to ask, Why do we ever employ anything but simples or expectant remedies, or methods intended to increase the vigor of the body or to restore a disturbed equilibrium? Why do we ever give supposed specifics? First, because our patients wish, nay demand, that such remedies shall be tried; and, secondly, in obedience to fashion. For, as you well know, there is a fashion in drugs and modes of practice; and for the doctor to ignore the latest fashionable treatment, or decline to use it, is to run the risk of being thought ignorant, narrow-minded, or wanting in liberality, and thus to lose the respect of the community, and even, let me say it, of his *confrères*. It matters not at all that he has seen remedies and modes of treatment brought forward and advocated in our great societies with scarcely a word of dissent or disapprobation, declared to be almost specific, recommended by high authorities, supported by plausible theories, and yet, after a longer or shorter experience, abandoned as useless or uncertain, and now chiefly remembered as having been sometimes followed by dangerous or alarming symptoms, and even *fatal effects*. There are people in the world who would rather die under "the latest treatment" than get well unfashionably.

The recommendations of a new remedy amount to this: "I was ill, I took something, and now, thank God! I am well." But the success of the specific is always found to be in inverse ratio to the virulence of the epidemic.

If the connection of cause and effect were immediate and certain, the "post hoc propter hoc" as clear and evident, let us say, as a chemical reaction, the use of drugs could no longer be looked upon as empirical.

But, as Dr. David Cheever says in his admirable Boylston Prize Dissertation on "The Value and Fallacy of Statistics,"—which I regard as a distinct dialectic contribution to medical science:

"The mere observation of simultaneous or consecutive occurrences, however great the number of cases, can lead to no definite results which may not be fallacious."

"Effects are ascribed to drugs which really flow from natural causes and are but the usual succession of the morbid phenomena; sequences are taken for consequences and all just conclusions confused."

The first great epoch in the history of medicine in modern times occurred, as I think, in the latter half of the seventeenth and the beginning of the eighteenth century. This may be said to have begun with the discovery of those important white corpuscles of the blood, and the perfecting of the lens of the microscope, by Leuwenhoek.

The other great names of this epoch are Sydenham, who gave us the present method, a rational empiricism; Boerhaave, at Leyden, who introduced the clinic and an eclectic practice; Haller and Morgagni, who taught the pre-eminent importance of the studies of physiology, pathology and anatomy; and others, such as Stahl and Hoffman, who also had clinics at Leyden, "whom human memory need not charge itself with."

Then it was that medicine, both in the schools and the practice, appeared for the first time before the modern world with something of the dignity of true science. Still the reasoning continued to be a fruitless induction, an attempt to explain the inexplicable and think the unthinkable, as was the case with Cullen and Brown. No one surpassed the stature of Herman Boerhaave who, in his farewell address to his pupils, declared "that man to be the first physician who knew how to wait for, and to second, the efforts of nature"—the true doctrine of the father of our art.

But at the close of the eighteenth came the greatest epoch-making single event in the whole history of medicine—vaccination.

I give this the first place among epochs in the history of our science, because then for the first time the fact appeared, that the noblest, the most beneficent, mission of medicine to mankind is in the saving of human life.

No one who will carefully review the frightful history of small-pox and dispassionately weigh the evidence, can hesitate to admit that, during the century of its employment, vaccination has been the indirect means of saving millions of human lives.

Excepting Jenner's own suggestion that this discovery might prove the clue to a new explanation and perhaps a new treatment of many diseases, no deductions of any value were made from it, and it was looked upon as a piece of fortunate empiricism. Jenner planted and died, but two generations and more were needed to ripen the fruit upon his tree.

In the very first years of the present century a new day dawned for the study of medicine when Xavier Bichat, by experiments upon animals, placed on an impregnable basis some most important facts of physiology and pathology, and introduced the subjects of histology and cell-biology. His too early death left the world upon the threshold of what have since proved in the hands of others, especially Virchow, to be most valuable discoveries. The monumental work of Rokitsansky in morbid anatomy should not be overlooked.

But Charles Louis — assisted doubtless by the practice of physical diagnosis and the employment of the stethoscope of Lænnec — made an epoch in medicine by the introduction of a method of precision never attempted before. Genius has been defined as a capacity for taking pains. Louis abandoned a lucrative practice and consecrated seven years to exclusive clinical and anatomical, or pathological, study. He instituted, as it were, a tribunal, before which were brought all the various systems and modes of medical treatment then in vogue.

Nature herself was, so to speak, placed upon the stand and questioned, and her testimony was found to completely refute the often conflicting evidence, often ill-digested, partial or prejudiced, upon which was based the medical practice of the civilized world. The solidism and atony of Cullen, the sthenia and asthenia of Brown, as well as the gastro-enteric theory of Broussais, all had to give way before the precise inquiries of Louis, and his rigid application of the method of statistical enumeration conferred for the first time upon medicine the right to be truly called an inductive science.

Louis was what Carlyle delighted to speak of as "a most lucid, veracious man." He inspired his pupils with his own fervent, unselfish devotion to scientific accuracy and truth; and we were most fortunate in our medical school, and in this Society, in having three splendid examples of his teaching in Shattuck, Bowditch and Holmes.

Louis insisted, and *demonstrated by post-mortems*, that in many, if not in all, maladies, notably in the three great scourges of the civilized world, namely, phthisis, typhoid fever and yellow fever, the course of nature was shown by analysis of the statistics to be uncontrolled by remedies.

But what then becomes of our definition that medicine is the art of healing the sick, which we must admit to contain the chief title which we have to the confidence of our patients? Must we stand hesitating and inactive by the bedside of mortal disease because we have been shown the uselessness of all specific treatment heretofore employed?

Louis himself answers this question when he says, "We can only hope for a moderate success even by the best adapted treatment," but this "does not warrant the rejection of an empirical treatment, however absurd or ridiculous it may appear, since it is against an unknown cause⁴ that our therapeutical agents are employed."

That is the point, "an unknown cause." It hath been as the darkness around Ajax:

"Give me to see, and Ajax asks no more."

When I was a young man the inspiration of the spirit of Louis was fully alive and recognized in the profession here. Jacob Bigelow, Wendell Holmes, and Benjamin Cotting, reverting again to the teaching of the Father of Medicine, and pointing to the excellent motto of this Society, "*Natura duce*," wrote and spoke about the "self-limitation" of diseases, the value of the work of nature in disease, and especially the pre-eminent importance of the study of nature's processes when not interfered with by remedies. Something doubtless of the spirit of Louis was felt in the community. At least persons of intelligence and cult-

ure regarded the autopsy with favor, and the request for a post-mortem was seldom denied except by those of foreign origin. This mode of thought was fostered and encouraged by the zeal of many of the younger men of the profession, who rarely allowed an opportunity to pass without *making an autopsy*, and using every argument to persuade those who were reluctant.

Henry Ingersoll Bowditch was a worthy pupil of a grand master. With the ardent enthusiasm of his nature he brought the spirit of Louis to the investigation of the phenomena of disease; he fired his pupils with his own zeal, as much as he drew them to himself by his benevolence, his devotion to the right and to truth, his generous impulses, his noble, unselfish nature. His absolute faith in the teaching of Louis remained, as I believe, to the last.

John Bernard Swett Jackson, an apostle though not a pupil of Louis, was one to whom many besides myself feel that we owe a debt larger than that to any other man, teacher or friend. For absolute devotion of heart and soul and mind to the study of diseased anatomy, no man ever excelled him. As a macroscopic pathologist he had no equal in this country; as a teacher, his almost boyish eagerness in examining and explaining nature's aberrations, her morbid and abnormal phases, was an inspiration which the most cold-blooded could not resist. He delighted in showing the "characteristic morbid appearances," and in dilating upon the uncertainties of diagnosis. He insisted that symptoms were frequently present and presumed to indicate a disease which could not be found at the autopsy, while, on the other hand, disease might exist of which the pathognomonic symptoms had been absent during life. He never troubled himself or his pupils with theories, having as great contempt for them as Sydenham himself; while, as to the microscope in morbid anatomy, he held similar views to those of Cheselden — William Cheselden, who says in his preface, "The study of anatomy as it leads to the knowledge of nature and the art of healing, needs not many tedious descriptions nor minute dissections; what is most worth knowing is soonest learned and least the subject of disputes; while dividing and describing the parts, more than the knowledge of their use requires, perplexes the learner and makes the science dry and difficult." You will see in Wendell Holmes's address to the students in 1867, that he, an enthusiastic microscopist and a learned anatomist, held much the same views as those of Cheselden.

Calvin Ellis was another earnest, patient follower of Louis. He also belonged to the class of lucid, veracious men. The conscientious thoroughness of his work was the admiration of all who knew him. If genius be indeed a capacity for taking pains, here was a man who possessed that kind of genius. His earnestness in the study of the physical signs and of symptoms, his enthusiasm in the clinic, his faith in the confirmation of the autopsy, his absolute veracity in the registration, these made him respected as a teacher, trusted as a guide. In dying his chief regret, often expressed, was that his immense collection of notes and observations, written in shorthand, could not be made useful to the world. It is to be hoped that the man may yet be found who will draw from this treasury the wealth which it contains for the benefit of science and for the honor of our profession.

"That colossal system of self-deception which has been the disgrace of medicine" must be swept away.

⁴ "It is obvious that we have present in all our formulae of vital phenomena, in health or disease, an *unknown element*, which no algebra or calculation can resolve." — Boylston Prize Essay for 1860, by David W. Cheever, M.D.

and with untiring zeal and devotion these men and others like them, following in the path marked out by the great master Louis, strove to place medicine in the position of a true inductive science; a science which is "the topography of ignorance."

Thus was laid here in Boston, as it were, the foundation of a temple of medical science. But to further raise this structure there was needed a vast body of painstaking, accurate observers, loyal to the truth at whatever cost, each of whom should place his stone upon the pile.

Thus, and then only, could the present method, the method of Sydenham and Boerhaave, a rational empiricism, be said to stand upon a philosophic basis.

But what is a rational empiricism? Perhaps I cannot better describe it than in the words of Dr. Amos Twitchell, of Keene, N. H., who, in 1807, in a little country village, single-handed, tied the common carotid artery and thus saved his patient's life; and of whom Dr. Bowditch wrote that "he was perhaps the most original mind our profession has produced in New England." Indeed, Dr. Twitchell was a man like Ian Maclaren's Weelum Melure, one to satisfy the panegyrist and historian of Frederick the Great. When asked by one of his admiring pupils as to the cardinal principles of his practice, Dr. Twitchell is said to have replied, "If the patient is cold, I warm him; if he is hot, I cool him, if I can; this is the alpha and omega of my practice."

Such a method may have much to do with the art of healing the sick, but it has nothing whatever to say to the science of medicine. It is rational, but it is also empirical. It is the supreme philosophy of common-sense.

As time has gone on much of the enthusiasm for the method of the famous physician of La Pitié has died out. Almost all that has remained of the idea of Louis, that it was possible out of systematized knowledge to make a science of medicine,⁶ has been the numerical part, which has lost all quality of verity since it has come to depend chiefly upon the observed effects of remedies. The notion still obtains that in some way cure is effected by the art of medical pharmacy; medical experience being one thing, and human belief another. It seems to be ignored that the numerical method of Louis as a test of the value of any mode of practice, is *sterile* without the autopsy.

For obvious reasons the post-mortem has been neglected, at least among general practitioners, and it appears in consequence that the art of healing has sought to be divorced from the science of medicine; the "allegation of the libel" being "desertion and non-support." And what has been the result? Medicine and physicians have forfeited the prestige that once was theirs. Scant respect is paid to the title of "doctor," and the degree of M.D. confers no special distinction. The regular physician is allowed little influence in forming public opinion upon medical matters. There are many men in large practice who do not care to have autopsies, and never publish any valuable notes or observations. There are many medical graduates of our universities who do not seek to connect themselves with this, nor any other, society for the advance of their profession. The conscientious student of the *science* finds little honor or profit in the practice of the *art* of medicine. "The present system

of medical expert testimony has degenerated into something which very much resembles a shameless and degrading farce." The councillors of this Society hold their meetings in a mean, dark, half-subterranean apartment in a narrow court of the city. And as to the progress of medical science, we have had an etiology which could not explain itself, a therapeutic largely dictated by fashion, and a statistic containing returns of "causes of death" which are a confession of ignorance, such as "heart failure," "dropsy," "asthma," "convulsions," and many more, which as you well know are most frequently merely symptoms of some undetected organic disease. Perhaps this is only one of the evils brought upon us by homeopathy, which, according to its inventor and founder, declares that diseases have *no material cause*, but consist in symptoms alone.

After all, what does it matter, since, as it seems, the decree of absolute divorce has been granted between the art and the science? It is not for us to cry "quackery!" upon any system, however absurd. The "tu quoque" confutes us.

More or less, in all ages and states of society, medicine has been the sport of fashion and the prey of delusion. In these days when all the world seems, as it were, to be singing the *ça-ira* in a French Revolution of thought and feeling, medical art has suffered in the general *débâcle*. The spirit of the age being the enjoyment of life and the accumulation of riches, the autopsy, which has only value for science, has become discredited, if not abhorred, by the community. It is a well-recognized fact that the hope of passing laws devised simply and solely for the advantage of medical science, or for protecting the stature of a medical spread of epidemic disease, well address to his pupils, cry being "Interference with the physician who knew, though it were possible that there ~~forts~~ be any ch in such matters." The search for specifics and panaceas has come to resemble that which went on, in the st of alchemy, for the philosopher's stone. It will seem at times as though men had been hypnotized by riveting the attention upon some shining fallacy of theory or practice. The adoption of specialties, while it has much to recommend it, inclines us to forget that the whole is always more important than any of its parts, and to put the infinitely little above the infinitely great. It is customary among physicians to prescribe in compliance with the prejudices of the time, rather than in accordance with the rational experience or observation of men.

Perhaps I cannot give a better illustration of my meaning here than by referring to the history of venesection. Nature herself in certain disorders indicates the advantage of the letting of blood. The practice has great antiquity to recommend it, having been employed by the "most learned and approved good masters" since, and very likely before, the time of Hippocrates; by Sydenham, Boerhaave, Louis, indeed by all the men who have marked the great advances in the art and science of medicine. At times discredited, again applauded, it has held its own and has outlived all systems and all theories.

In the early part of the present century the gastro-enteric theory of Broussais, who was followed by Rush in this country, lead to the practice of indiscriminate

⁶ "In mathematics, we have the fact that geometrical theorems grew out of empirical methods." — Herbert Spencer.

⁶ In Massachusetts the law does not protect the physician who hesitates to reveal the secrets of the sick chamber when called to give evidence upon the witness-stand.

and free use of the lancet; but Bouillaud, in France, with his bleeding *coup sur coup* in pneumonia, introduced a still worse method, so that Dr. Tully wrote, "the lancet is a weapon which annually slays more than the sword."

Those who were students in the Paris hospitals in the early fifties will remember the pewter porringer on a shelf at the head of every bed to receive the blood of a patient; and if you will examine that admirable work, "Le Guide du Medecin Practicien," of Valleix, Baillière, Paris, 1853, you will find under the head of treatment, "La Saignée" given the first place in nearly every disease in the five volumes. These were bad fashions.

But for more than forty years the practice of venesection has entirely gone out of use in our largest hospitals and among our most distinguished physicians. So much is this the case that the suggestion to "bleed" is met by doctors and patients with incredulous surprise, as though it were question of a capital operation in surgery. Every radical departure in treatment has been supported by some theory. The "change of type" theory, which grew, I believe, out of the Brunonian system, was brought forward to uphold the neglect of venesection. This theory was another of those vague speculations, chiefly dialectic, whose cloudy futilities have from time immemorial obscured the pathway of medical science. It went into the dust-heap long ago, but the practice of bleeding, theory or no theory, has been discredited.

In that most excellent work, "The Principles and Practice of Medicine," by William Osler, New York, 1894, we read, "Pneumonia is one of the diseases in which a timely venesection may save life." And speaking of "Emphysema," he says, "On more than one occasion I have saved the lives of persons in this condition by venesection." And under "Chronic Valvular Disease," "This is the occasion in which a timely venesection may save the patient's life." Also, at page 1019, Osler states that the life of Dr. Weir Mitchell, when a young man was saved by free bleeding in sun-stroke. I can recall in no modern work on "Theory and Practice" or "Therapeutics," a similar statement in regard to the effect of any drug.

I would say to you in the emphatic language of Rufus Choate, "Gentlemen, there is not one jot, not one tittle, not a scintilla of evidence which can impeach the testimony of this witness." In the cases cited by Osler the course of nature tends inevitably and swiftly to death. The effect of the remedy appears as indisputable as that of chemical reaction. For what purpose are we physicians if not to save human life, if it be in our power to do so! Are we to stand by and see our patients dying—as it were drowning, and we refuse to throw the rope which we hold in our hands—in obedience to the dictation of a heartless, senseless fashion!

(To be continued.)

THE NEW WOMAN AND THE WHEEL. — A writer in a St. Louis contemporary says that the bicycle "is equally if not more beneficial to young girls with scanty, delayed or irregular menstruation, who are developing into manhood, than any other deviation from the normal that the female sex is afflicted with." The opponents of the wheel contend that this is just the trouble, that girl riders develop into manhood.—*Medical Record*.

STANDARDS OF FORM AND COLOR-VISION IN RAILWAY SERVICE.¹

BY CHARLES H. WILLIAMS, M.D., BOSTON.

By normal vision is meant such acuteness of perception of form by the eye that it can recognize letters or symbols which subtend a visual angle of five minutes, and whose breadth is throughout equal to one-fifth of their height. This standard was established years ago by Prof. H. Snellen, of Holland, who found by a large number of experiments that the average healthy eye could easily read such letters. Many eyes, especially those of young people, have a greater acuteness of sight than this, but, on the whole, it fairly represents the average vision of a healthy emmetropic eye, and has been accepted both in Europe and in this country as the standard in general use.

The letters of Snellen's test-types, to be read at a distance of twenty feet, should be three-eighths of an inch² in height, and if the person under examination reads them with each eye separately at that distance without glasses, the other eye being covered by a card held firmly against the nose, we call his vision normal, or $\frac{20}{20}$, in each eye. If he is obliged to approach to ten feet from the letters in order to read them we call the vision one-half of normal, or $\frac{20}{40}$. In practice letters of different sizes are printed on the test-cards and over each line is printed the distance at which it can be seen and read at the standard angle of five minutes, that is by a person having normal acuteness of vision. If we find that at twenty feet the smallest letters which can be easily read are on the forty-foot line the vision will be $\frac{20}{40}$, or one-half. The acuteness of sight is measured by Snellen's formula $V = \frac{d}{D}$, in which V stands for the vision; d , the distance at which the test-types are recognized; D , the distance at which they can be seen by the normal eye under the standard angle of five minutes.

In ordinary disease, or in errors of refraction, we use these test-types to measure the progress of the case, or the best results from glasses; but in certain forms of employment, as in the railway service, in which keen vision is required, they are used to decide whether a person is qualified for the work he will have to do, and in these cases the question at once arises as to what acuteness of vision should be required for such work. A single standard will not answer. A greater acuteness of sight will be necessary on the head end of a train than would suffice for switchmen. Again, when a man applies for work in connection with the operation of railway trains he should be required to have a greater acuteness of vision than the amount which will suffice to allow him to continue the work with which he has become thoroughly familiar after years of service. Thus we should have two standards, the higher for entrance to the service, and the lower, which would be within the safety line, and would be sufficient to allow a continuation of employment.

The principal hardships to employees in vision-tests has come, not from enforcing a high standard for en-

¹ Read before the Boston Society for Medical Improvement, February 8, 1897.

² The measurements in this paper are given in inches instead of in the metrical form, as the former are in general use among the railroads.

trance into the service, but from discharging men after years of faithful work, for some defect which the railroad company might have discovered at the time they were employed, if a proper examination had been made at that time. Therefore, it is important, both to the company and to the men, that the methods used and the standards adopted should be such as to exclude men who are not fitted for the work, and to prevent their wasting time in learning a business they may have to abandon; also, in cases of defective sight or color-sense acquired in the service, to enable the company to relieve such employees, or transfer them to other duties, before they have become a danger to themselves, their fellow-employees or the travelling public.

If we look through the standards required to-day on various railways and in various countries, we shall at once see in what an unsatisfactory condition this matter now stands. In some countries the government regulates the matter, in others the companies adopt their own rules; and it is noticeable that some of the highest standards are those voluntarily adopted by the roads themselves.

In Holland, these matters have been more carefully worked out than elsewhere, and oculists of the highest standing in their profession have been called on to formulate rules for these examinations and to fix the standards. They require for Class A, enginemen or firemen, with both eyes open, normal vision; with each eye separately, the other being covered, normal vision in one eye and not less than one-half in the other, without glasses; also normal refraction. For Class B, station-masters, conductors, brakemen, switchmen, etc., with both eyes open, normal vision without glasses, free from hypermetropia of more than one dioptre; with each eye separately, in one eye normal vision, in the other not less than one-fourth, without glasses. The vision is measured by Snellen's test-types.

In England, a committee of the British Medical Association, after careful investigation, recommended in their report in 1892, for Class A, engine-drivers, cleaners, firemen, signalmen and pointsmen, in one eye normal vision and refraction, in the other eye not less than one-half of normal vision, without glasses. For Class B, all other situations in the executive service concerned with the moving and signalling of trains, with both eyes open, visual acuteness of not less than two-thirds of normal, without glasses, provided that neither eye has less than one-third of normal vision without glasses, using Snellen's test-types.

In Belgium, for Class A, in one eye $\frac{2}{3}$, in the other not less than $\frac{2}{3}$; for Class B, in one eye $\frac{2}{3}$, in the other not less than $\frac{1}{3}$.

In Bavaria, for Class A, $\frac{2}{3}$, without glasses, is allowed; this class here includes all outdoor employees.

On the New York Central and Hudson River Railroad, for a first-class certificate, vision of at least $\frac{2}{3}$ is required; but if one eye has $\frac{2}{3}$ and the other $\frac{1}{3}$, it will answer. For a second-class certificate, for yard service only, not less than $\frac{1}{3}$ is required; but if one eye has $\frac{2}{3}$ and the other $\frac{1}{3}$, it is accepted for a second-class certificate. On the Pennsylvania System $\frac{2}{3}$ in one eye and not less than $\frac{1}{3}$ in the other is considered satisfactory, with or without glasses. On the Burlington System, for entrance into the engine service, $\frac{2}{3}$ in each eye is required; and for the train and yard service $\frac{2}{3}$ in one eye, and not less than $\frac{1}{3}$ in the

other eye, without glasses in all cases; each eye being tested separately.

It will be seen from the above that the standards of vision vary in different places from $\frac{2}{3}$ or normal vision in each eye, down to $\frac{1}{3}$ in each eye for the first class. In some cases provision is made for re-examination, but in many places no separate standard is required for this. The test in general use is Snellen's test-type, although in England some roads use the army test-card, with dots instead of letters.

The principal objection that I have found to the ordinary Snellen letters, for this work, is that they are all printed on one card, and it is not difficult for men who are to be tested to provide themselves with copies of the card in order to memorize the letters. In one case a man read easily the XX foot line at twenty feet who could not read either the XXX or XL line at twenty feet when called on to do so unexpectedly by the examiner. In order to overcome this difficulty, and also to provide a more convenient form of test-card, I had the letters of standard sizes printed on a series of separate cards, one line on each card, and for each distance had three cards with a different arrangement of the letters on each. In testing a person, one of the XX foot cards is placed in a good light twenty feet from him, and he is asked to read it; if he does so correctly, another of the XX foot cards is shown for a second trial. He cannot tell which of the cards he will be asked to read, so that even if he had memorized them all, he would have to see the letters in order to read the cards correctly, and as there are no letters of a larger size on the same card he could not recite from memory the smaller letters by means of the larger letters that he could see. If he cannot read the XX foot line at twenty feet, then the XXX, the XL, the L or the LXX foot cards are shown in succession until letters are found that he can read; or if he cannot read the LXX foot line at twenty feet he is brought nearer until a point is found where it can be read; or if he cannot see it at any distance, the fact is so noted. This test has been in use on the Burlington System since 1893, and has given good satisfaction.

I have recently been experimenting with another test-card with figures made to represent a line of semaphore signals, such as are often placed on a bridge crossing the tracks, as at the entrance to a union station. On this card the length and breadth of the arms correspond to the height and breadth of the Snellen letters for XX feet, and also correspond when looked at from a distance of twenty feet to the size of a standard semaphore arm when seen at a distance of half a mile. I find when the relative visibility of this signal card is compared with the corresponding Snellen letters, that the card of signals the same size as the XX foot letters can be seen clearly as far as the XXX foot letters. For, with signals, the only point is to recognize quickly and surely the position of the semaphore arm, as to whether it stands horizontally at danger, or at an angle with the horizontal at safety; whereas with the letters small differences of shape must be recognized, and the letters C, G, D and O are easily confounded; such mistakes should not reject a candidate. We can therefore safely allow a less degree of vision as tested by letters, especially on re-examination, than $\frac{2}{3}$, and yet be within the safety limit for signals.

A railroad company should require normal vision, $\frac{2}{3}$, in each eye, without glasses, and less than two

dioptries of hypermetropia of all persons seeking employment in its engine service who will be required to act at any time as enginemen or firemen. Plenty of such men can be had, and the company cannot afford to accept and educate men who are lacking in normal vision when they begin their work. After years of service the requirements may be reduced for Class A to not less than $\frac{3}{8}$ of normal vision in one eye and $\frac{4}{8}$ of normal in the other, each eye being tested separately without glasses; but less than this should not be allowed on the head end of a train.

The same standards should be required of men in signal towers and in charge of interlocking signals and switches and drawbridges; but for the general train and yard service lower standards may be allowed. For entrance to the train and yard service $\frac{3}{8}$, or normal vision in one eye, and not less than $\frac{4}{8}$ in the other, without glasses, should be required. After years of service, on re-examination, this might be reduced to not less than $\frac{3}{8}$ in one eye and $\frac{4}{8}$ in the other, without glasses.

In addition to reading the test-letters by candidates for employment, a simple test for refraction should also be used in all cases. We may leave out of the question the conditions of myopia and astigmatism, for, if present in any amount, they would cause enough defect in sight to bring the vision below the required standard; but a young man of twenty-one years of age, or thereabouts, may be able to read easily the XX line at twenty feet with each eye, and yet have a hypermetropia of two dioptries, or more, which by the time he is forty-five years old, or sooner, will reduce his visual acuteness for distant objects below the standard required, and it is not just to such men to accept them for the service and then retire them when they are too old to learn another business, because they cannot come up to the visual standard required without glasses, although they may have had normal vision in each eye when they applied for work. Such hypermetropia can be easily detected by asking the applicant to read the XX line of test-letters on another card at twenty feet, while looking through a convex lens of two dioptries, or eighteen inches focus, each eye being tested separately. If with each eye he can read the letters correctly through this glass, he should be rejected, for it shows he has a hypermetropia of two dioptries, or more, which, when his presbyopia becomes apparent, will be sure to impair his distant vision unless glasses can be used.

I recently had a case to examine where the vision of an engineer had been reduced to three-tenths of normal in each eye. There was no other trouble except a hypermetropia of three dioptries in each eye; and with proper glasses the vision was brought up to normal in one eye, and nine-tenths of normal in the other. He was transferred to other work in which he could use his glasses; but in this case the simple test with a convex glass would probably have shown the trouble at the first examination for entrance to the service, if one had been required at that time.

A periodical re-examination of the vision should be required of all men employed in the operation of trains or signals every three years, for the sight is often impaired by disease of the inner structures of the eye that may show no outward change; and such re-examinations should be made before promotion, after serious illness or injury, after accidents which might have been due to defective sight, or when from exces-

sive use of tobacco or other cause it is deemed necessary. The certificate of examination given to the man should state the date of examination, the occupation which the certificate covers, and whether or not any defect is found in acuteness of vision, color-perception or hearing, and the certificate should be signed both by the examiner and the person examined. If the first examination is made by a competent person, according to approved methods, at the time of employment, no repetition of the tests for color-vision will be needed, unless it is found that the acuteness of form-vision has become impaired; for in the cases of acquired defect in color-sense an accompanying defect in sight is found which will be brought out by a repetition of the test with letters on the test-cards. In such cases it may be well to repeat the color-tests, and to refer any doubtful cases to an approved expert. In cases of congenital defect in color-sense there is generally no impairment of the acuteness of form-vision.

In all examinations for sight, care should be taken to see that uniform and accurate test-letters are used, for within a month my attention has been called to sets of test-letters recently published in which there was a considerable variation in the size of the letters to be used at twenty feet on different cards issued by the same firm. Again, the illumination of the letters should be as clear and constant as possible; the card should be hung where it gets the daylight full upon it, but not in the sunshine or where the person reading it will have to look directly toward a strong light.

As to the relative frequency of defects in sight and in color-sense, we rejected on the Burlington in six years 176 cases for defective color-perception and 344 for defective sight, most of these cases being applicants for positions in the service. In general it may be said that the number of cases of defective sight found on first examination for entrance to the service will be more than twice the number of cases of defective color-sense, but on re-examination defects in form-vision will be found while those for color will be extremely rare.

The instructions of the Pennsylvania Railroad in regard to tests for vision, etc., also provide for an examination of the field of vision and the range of vision. It does not seem to me that these tests are necessary, especially considering the way in which they are usually made; and in the thousands of reports that were sent to me on the Burlington, where somewhat similar tests are used, there was not a single case where a man was rejected for limited range or field of vision, in which the acuteness of sight was up to the required standard. The examination on the New York Central and Hudson River Railroad does not include either a test for the range or field of vision. It is, however, well to have a reading-test in order to make sure that the person examined can read both print and written train orders at the ordinary distance. And I have known an engineer who was found by this test to be unable to read, although he had normal vision, knew his letters and could sign his name; he was in the habit of having his fireman read all train orders to him, but when his condition was discovered he was laid off until he could learn to read, and write more than his signature.

In regard to the use of glasses, the instructions of the Pennsylvania Railroad say, "If one eye has $\frac{3}{8}$ or 1, and the other eye not less than $\frac{3}{8}$, or $\frac{4}{8}$, with or without glasses, the sight may be considered satisfactory"; but no statement is made as to whether this

will be satisfactory for an examination for entrance to the service, or only for re-examination, or whether glasses will be allowed on duty. It will be found in practice that glasses for distant vision cannot be worn on duty by enginemen and others whose duties require them to work out of doors in all kinds of weather; for steam, rain, smoke and snow interfere seriously with their use. For this reason the acuteness of the distant vision for these men should always be tested without glasses. With cases of simple presbyopia it is different; here the distant vision remains unimpaired, and when glasses are needed for occasional use, as in reading, they are not incompatible with good service. The presbyopia will have to be very considerable before it will interfere with the telling of time by the watch or the reading of steam or water gauges, without glasses.

The standard examination for color-vision should include three things: (1) the naming of colored signal flags, and using them as test-objects for the Holmgren worsteds; (2) a test by comparison of colors by the Holmgren worsteds; (3) a test with colored lights as seen through openings of regulated size, which will form small images on the central part of the retina. The acuteness of color-vision varies considerably from a normal standard, as does form-vision. We may have a feeble color-perception, an incomplete loss of color-sense, generally for red and green, or a complete loss of perception for these colors, and in rare cases a complete loss of all color-perception, in which the solar spectrum looks like a gray smear of varying shade but no color. The object of our tests is to discover the extent and character of the defects and whether they are sufficient in amount to disqualify, according to the standards adopted.

The test with flags shows whether the man can give the right name to the flags and can tell their use and meaning. It will also be desirable to use the flags as test-objects with the worsteds. It will often be found that correct names can be given to the flags even when considerable defect of color-perception exists, for such men have learned to give a certain name to a certain perception; but when we come to use each flag, red, green, or white separately as a test-object and request that all colors be selected from the heap of worsteds which look like the flags, we may get among the reds a green or other color selected as looking like the red flag, or *vice versa*, in other words, with colors of certain intensities or shades, there may be an inability to distinguish between the red and green.

The test by comparison of colors, without naming them, selecting from a large number those which appear to the applicant like certain test-skeins, light green, and pink, according to the method proposed by Professor Holmgren, is the most satisfactory and easily applied of all the good qualitative tests; but it does not give a quantitative test, and does not give a sufficient test for small central scotomata such as occur in tobacco cases. The test by Holmgren's worsteds alone will not in every case detect a serious defect in color-perception.

I have had recently a man who passed both the Holmgren and the Thomson tests without making a single mistake and who selected his colors without hesitation, but when examined by colored lights transmitted through small openings, or even with switch-light lenses before the lamp at twenty feet distance, he called a red light white in four different cases; he had a central defect in the retina, probably caused by

the use of tobacco in excess, yet the area of the affected retina was so small that the retinal image of the worsted or the flags fell partly on the affected area and partly outside of it where the color could be at once recognized, but when the retinal image was reduced in size, as with the lights, it fell entirely within the affected portion and red lights were called white and sometimes green.

It will not do, however, to substitute the test with such lights for the Holmgren test, for the lights give little chance for comparison or for the selection of confusion colors; and for ordinary cases of congenital color defect it would take a long and tedious examination to reach the same result that could be arrived at more quickly by the worsted test.

On the other hand, the test with lights, with regulated openings, should be used in addition to the worsteds, as is required in Holland. Their regulations for testing the color-perception of railway employees require a quantitative test in every case by Donders's method. In his instrument the light from a standard candle is allowed to fall on a disc carrying red, green, blue and ground glasses, and in front of this disc is a diaphragm with openings of 1, 2, 5, 10 and 20 millimetres in diameter; the colors can be changed by rotating the disc, and the man is requested to name the colors as seen through the smallest opening placed five metres from him. If he cannot do this, he approaches the instrument until the color can be distinguished, or a larger opening can be used. Professor Donders accepted the formula for the acuteness of color-perception as $= \frac{a}{A}$ in which a is the visual angle at which the person examined sees the colors, and A is the angle at which the examiner sees them. If the examiner can see the red and green lights through the one millimetre opening at a distance of five metres and the person examined only sees them at one metre his color-perception would be one-fifth.

In these cases we have to depend on the acuteness of color-sense in the eye of the examiner as the standard with which the applicant is compared, and this standard may vary considerably in different persons. Again, the distance of the candle from the colored glass is an important factor, and the red can be seen by normal eyes with the candle at a greater distance from the glass than with the green. In all signal lanterns, however, the light must remain at the same distance from the lens, so that in testing railroad employees we may disregard this difference. Instead of taking so small an opening as one millimetre for the standard test, it will be found better to use a two-millimetre hole, or about $\frac{5}{16}$ of an inch, and place the person to be examined at a distance of twenty feet from it. In this case the opening will subtend a visual angle of one minute at the eye, and will correspond to the width of the letters on the xx foot Snellen test-card used for that distance. If we make the other openings in our diaphragm $\frac{7}{16}$, $\frac{9}{16}$, $\frac{3}{8}$, $\frac{1}{2}$, $\frac{5}{8}$, and $\frac{3}{4}$ of an inch in diameter respectively, we shall have a series of diameters that will nearly correspond to the width of the series of letters on the Snellen test-card, and which at corresponding distances would subtend the uniform angle of one minute.

If we consider as a sufficient standard for this test the ability to recognize red and green, either alone or combined with London smoke-glass to vary the intensity of the light, and also white light, either alone or combined with the London smoke-glass, all seen

under this standard angle of one minute, we can then use the other openings in the diaphragm to give a fraction which will represent the amount of color-perception as compared with this unit, just as in the case of form-vision. For instance, if the normal eye recognizes easily the colors through the two millimetre (or $\frac{2}{84}$ inch opening) at twenty feet, and the eye examined only distinguishes them when the $\frac{4}{84}$ opening^a is used, we call his color-perception one-half of the standard. This is not exact and we cannot get with color-perception by our ordinary tests the same fine gradations of acuteness that we get with form-vision. We also find many eyes whose color-perception is more acute than this standard, just as we find eyes that can see the XX line of letters at a greater distance than twenty feet. But it furnishes us with an easy test having a direct relation to the standard of form-vision, and one which is useful in detecting defects in the central portion of the retina.

About five years ago I made an instrument on this principle which has given satisfactory results, and with it the standard switch-light lenses and semaphore glasses can also be used as confirmatory tests. In a paper by Dr. Nuel, of Liege, published in 1895, he states that in Belgium in the confirmatory test they consider the color-sense as sufficient if the applicant distinguishes red and green through an opening of two millimetres at five metres distance when lighted by an ordinary kerosene lamp. In Holland, they require for color-sense in enginemen and firemen a power of distinguishing colors with both eyes open, of not less than four-fifths, or, in each eye separately, not less than one-half; and for other specified employments a color-perception of at least three-fifths with both eyes open, or not less than one-fourth in each eye alone. For re-examination, in the first class, the standard is dropped to at least three-fourths with both eyes open, or at least one-third with each separately; and in the second class, with both eyes, to at least two-thirds, or, with each eye separately, to at least one-fourth; and Donders's instrument is required to be used in all these tests. I used a Donders's instrument, made by Kaagenaar in Utrecht for some time, but did not find it so convenient or satisfactory as my instrument with the larger openings and greater number and variety of glasses.

Even with the Holmgren worsteds it is possible to make a distinction between some of the greater variations in color-sense; for if a person is hesitating, picks up some confusion colors and compares them with the test-skein, perhaps selects them and afterward discards them, or picks up some of the true colors and after comparison rejects them, finally selecting none of the confusion colors, it shows that he has a feeble color-perception; if he selects with the greens some of the confusion colors, but with the pink or rose skein makes no mistake, it shows he has an incomplete defect; but if with the green skein he selects confusion colors in addition to the greens, and with the rose skeins selects with the rose colors some blues or violets, it shows he has a complete defect for red; or if with the rose skein he selects in addition to rose colors some greens or grays, it shows he has complete defect for green.

On the Burlington System I found it best to have

^a The sizes of openings in this series were chosen because twist drills of these sizes were easily obtained and gave holes that at the respective distance very nearly subtended the standard angle of one minute.

each of the 117 colors of the Holmgren sets marked with a numbered brass tag, which could be used to make a record of the colors selected by the applicant, just as in the Thomson's test, and each set being carefully prepared in my office the numbers and colors were uniform for the whole system, so that when the results of each examination were forwarded to me for approval they could be easily checked. It is necessary in this work to have the general supervision placed in the hands of some competent person who can see that the examiners are properly instructed, that they carry out their directions, and that the tests they use are uniform and are kept in good condition; otherwise there is danger that the examiners will become careless or that the condition of the cards and colors will deteriorate so that they cannot be relied on to give proper results.

So long as the red and green signals are used for night work (and no other colors are better adapted to this use), no applicant should be accepted for service in a position which will require him to use such signals, who has incomplete or even feeble color-vision, and if these entrance examinations have been thoroughly carried out, according to Holmgren's directions, and also with transmitted lights, there will be no need of a repetition of these color-tests, except as before stated, where the form-vision has become impaired or where for some special reason it seems best to repeat the examination.

The tests for both form and color-vision should be made when the man is not fatigued by a long tour of duty or exposure; for it has been found that the acuteness of both form and color-perception is diminished after two hours or more of engine work; after long runs and unusual exposure this temporary reduction in acuteness may be considerable and it furnishes an additional argument for insisting on a high standard for such service. If one-half of normal vision were to be accepted as a minimum in each eye when the person was rested and in good health, the conditions of service might easily reduce this to far below the danger point, but if a high standard is required the vision may be temporarily reduced by fatigue without becoming dangerous.

In a report on the Sanitary Service of the Railways in Holland, presented to the International Conference in Amsterdam in 1895, it is stated: "Experience has shown that since the examination for admission has been carefully made, the re-examinations have shown scarcely any incapable men. It is also to be noted that the employees themselves in general recognize the utility and importance of these examinations." In a letter from one of the officers of the Burlington System, written to me November 18, 1896, he states that the operating officers of that system thoroughly approve of the examinations for entrance to their service, which include not only the tests for sight, color and hearing, but also a general medical examination, which is made by the medical examiners of the road, who are all well qualified medical men; and he also states that the general character and efficiency of the employees has been improved by these examinations, which are fairly and thoroughly made.

It seems to me that more can be accomplished in the way of improving the standards and methods used for testing sight, etc., by showing the operating officers of the railroads that it is for their own interest and for the interest of their employees to have such tests

carefully made, and to use such methods as shall be just and efficient, rather than by trying to force measures on the railroads through legislation, which is apt to be crude, and is met with opposition on the part of the road, and on the part of the employees, as being directed against their personal interests; whereas proper methods rightly applied should meet with the approval of both officers and men.

THE PROGNOSIS AND DURATION OF ATTACKS OF MENTAL DISEASE.¹

BY HENRY R. SIEDMAN, M.D., BOSTON.

THERE is no department of mental medicine that more closely concerns the general physician than the prognosis of insanity, as it is upon this point that his advice in such cases is oftenest asked. At the same time there is no other branch of the science with which he is less familiar. In fact, this paper is an endeavor to reply to requests from a number of practitioners for enlightenment in this direction.

Much of what follows is therefore an old story to the alienist, and perhaps to the neurologist. The much-mooted question, however, as to what constitutes acute and what chronic insanity, a matter of practical interest in the treatment, classification and disposition of the insane individually and *en masse*, as well as certain facts relating to the duration of acute attacks, both of which should be subjects of interest to those physicians whose work is more exclusively among the nervous and insane, will also be considered, as they seem not to have received the attention which their importance demands. But little reference will be made to the life-histories of the insane as regards *permanent* curability, as this is chiefly a clinical consideration of the immediate outcome of single and especially initial attacks and only in small part a statistical inquiry.

Statistics, although useful in elucidating other points relating to insanity, are of little help in prognosis. About all that can be gathered from them that is of real value on this point is the duration of hospital cases, and the fact that, as a general rule, those which are of short duration and are admitted early in the disease, are the most likely to recover. There are, to be sure, tables which give the number of recoveries from different forms of insanity; but as their classification is different in each hospital, only the results in the principal varieties form a sufficient aggregate for making an estimate. Hospital statistics, moreover, cover but a part of the ground, and a vastly different idea of the prospect of cure would prevail if the undoubtedly large number of cases (chiefly of melancholia), which recover without going to an asylum or even (as Blandford thinks) to a doctor, could be included.

Another complication which vitiates statistics of reported recoveries is recognized by asylum physicians generally, and that is the personal equation of the observer. One superintendent will fully believe a patient to be cured whom another would regard as simply greatly improved; and it occasionally happens that two hospitals in which the same class of patients are received, both of which are managed in practically the same manner, and in which the treatment and

care of the inmates is materially the same, will show a decided difference in the proportionate amount of reported recoveries, which can only be accounted for in this way.

Again, patients often recover and remain well while in the hospital who break down very soon after their discharge on attempting to take up their old life, thus showing that their recovery was only relative to their surroundings—a hospital recovery. Such patients have not recovered in the true sense of the word, and as it is understood as regards other forms of disease.

The great scientific value of the statistical researches of Thurnam, Hack Tuke and Earle in the curability of insanity cannot be gainsaid, but the small percentage of permanent recoveries in institutions for the insane thereby established, certainly has not stimulated us to work for the cure of separate attacks with the same zeal and interest that have led to decided advances in the treatment of physical disorders, and which alone can make permanent cures more frequent. On the contrary, a somewhat pessimistic attitude toward insanity has resulted, and endeavors for the best provisions for the mass have overshadowed the investigation of separate cases—the study of the needs of the individual and the possibilities in the way of his cure.

Sir Dyce Duckworth, in a recent address² upon "The Prognosis of Disease," remarks that at the present time, and for many years past, in spite of the extraordinary advances made in all branches of the sciences on which medicine depends—in spite, too, of the high degree of cultivation to which the art of medicine has attained in the last years of this century—the attention of physicians has been somewhat inadequately directed to the subject of prognosis in disease. He might well have added that in no department is prognosis more imperfectly understood than in that of mental disease. The principles—the elements—of prognosis are wanting, and therefore the alienist is practically at sea in many cases of functional mental disorder, and has to fall back upon empirical predictions by symptoms or sets of symptoms, which are often set at naught by some unexpected change in the course of the disease. To be sure, this happens often enough in physical disorders; and to be guarded in one's prognosis is the A B C of instruction in the practice of medicine. But nowhere is this caution necessary to such an extent as in functional disorders of the mind; and it is safe to say that the longer the alienist lives the more he despairs of making the right prognosis in individual cases, and the more he is inclined to "hedge" and to generalize.³ The chief source of the difficulty is our ignorance of the pathology of insanity, no theory of which has a known demonstrable material basis in actual cerebral lesion, nor in specific physical manifestations, the steps of whose development are indicated by pathognomonic symptoms following a definite course. The array of classifications of insanity to which each new observer adds still another combination, bears witness to this uncertainty.

² Presidential Address before the British Medical Association, British Medical Journal, August, 1895.

³ Since the above was written, the writer chanced to read Clouston's advice (Mental Diseases, p. 116): "Be guarded in giving a prognosis in almost every case. The greater my experience becomes the more guarded I am. Some of the most favorable cases will deceive you, while some that look the most hopeless will recover, as in the case of B. S. A., a patient of mine who had been seven years melancholic, suicidal and sleepless, and who recovered at seventy-four and is now quite well and doing her household work."

¹ Read before the Boston Society for Medical Improvement, April 6, 1896, and the American Neurological Association, June 4, 1896.

The pure psychoses are similar in this respect to the neuroses that have no known anatomical lesion. For example, although we know that true epilepsy is not susceptible of permanent cure, and to that extent we can make an accurate prognosis, we can rarely be sure that this or that indiscretion in the way of fatigue, or exposure, errors of diet, etc., will precipitate a seizure, how severe it will be when it comes, how soon or how frequently it will be repeated, and what the indications are of the approach of the epileptic status with its attendant dangers. The course of neurasthenia, also generally chronic, but often varied by alternate improvement and relapse, with occasional cases of recovery, offers us the same temptations to make specific prognoses based upon empirical generalizations.

Far different is the case with structural mental disorders having a known macroscopic lesion, such as general paralysis of the insane or post-paralytic insanity. The confidence with which, when once he has become satisfied of a diagnosis of general paralysis from unmistakable symptoms and clinical history, the alienist can predict from the first in many cases, not only the steps of progress in the disease but its approximate duration, is a refreshing contrast. He is rarely deceived by its decided remissions of almost complete rationality and general good health into making encouraging predictions, as he often is in the intervals of insanity of varying length which occur in acute attacks of ordinary melancholia or mania.

Before proceeding to details, a rough estimate of the probable results in the way of recovery is best taken from Thurnam's statistics which, although small in the number of cases, are considered to be of especial value, as he was able to trace the after-history of each patient who had been at the hospital *in whom death occurred*. They are as follows: "In round numbers, of ten persons attacked by insanity, five recover, and five die sooner or later during the attack. Of the five who recover not more than two remain well during the rest of their lives, the other three sustain subsequent attacks during which at least two of them die."⁴

The powerful influence of heredity was first to be considered. It is a general belief, both among members of the medical profession and the general public, that the inheritance of a tendency to insanity means impossibility of recovery from an attack of that disorder; on the contrary, strongly hereditary cases are often the most curable, but they are more likely to relapse than are those in whom the hereditary tendency is absent. Therefore, we should expect hereditary insanity to be shown chiefly in the recurrent, periodical and alternating forms; and this is the case. A bad family tendency of this sort may be shown in actual and marked insanity of certain members, while the rest are sound and strong and appear to have the normal amount of resistive power to disease. This, however, is a better inheritance than less distinct mental disease and more unsoundness and a low state of mental and bodily health *in the family generally* in the forms, for example, of various neurotic disorders, convulsions in childhood, weak-mindedness, bad habits and propensities and physical defects.

The time of life also modifies the prognosis; as in physical so in mental disease the young, especially females, are far more likely to recover than the mature and the old, setting aside cases of imbecility and constitutional moral obliquity. It has been estimated

that 63 per cent. of the recoveries from insanity take place before the age of twenty-five. At the same time the young are more subject to relapses, owing to the fact that bad heredity is most likely to operate in adolescence.

The menopause is another period of life at which many cases of insanity recover; but the disease is usually of long duration, not ending until the cessation of the menstrual function is complete. It must be borne in mind, however, that genuine climacteric insanity is rare, as cases in which the menopause is unmistakably the sole or even the chief cause of the trouble are far less common than is usually supposed.

Old age, on the contrary, is obviously the most unfavorable time for an attack of insanity; but here it is death from exhaustion that is to be feared rather than death of the mind alone. Even at this time of life, however, there is some risk in predicting that recovery is impossible, as it is among the aged that the marvelous cases are occasionally met with, of complete cure of acute melancholia in which exhaustion seemed inevitable from the extreme agitation, depression, refusal of food and consequent emaciation. Such miracles have few counterparts in physical disease.

A good physical condition just before the trouble is a less favorable sign than might be supposed, as it is usually the mild cases of long standing and slow progress to the active stage of the disease or to the more pronounced symptoms, in which the bodily health is but little disturbed. On the other hand, the acute, severe, rapidly developing, and for the most part presumably curable cases are often preceded by a season of reduced physical health and strength and loss of flesh which continues throughout the acute stage.

The natural mental capacity also makes quite a decided difference in our prognosis, as a person with a strong and active intellect and even keen sensibilities before the attack, seems to offer greater resistive power to disorders of the mind when once established than does an imperfectly developed mind and an insentient nature.

The immediate cause of an attack, when well limited and appreciable, which is not often the case, indicates a good chance of recovery; for example, sudden bereavement, shock, accident, money loss, the puerperal state, lactation, etc.

Treatment affects the prognosis in no small degree, especially the time of its adoption, the patient's chances growing fewer the longer it is delayed. It is needless to emphasize by statistics this well-established and well-known fact of the great importance of early treatment (not necessarily that of an asylum) away from home. The kind of treatment has also a decided influence; and the greater prevalence, both within and outside of institutions for the insane, of care and treatment directed to the needs of the individual patient, is sure to be a most potent factor in increasing the number of cures, preventing relapses and relieving the chronic cases. The practice which is still largely unavoidable in public institutions for the insane, of placing acutely violent patients in a perhaps overcrowded ward for obnoxious and equally excited patients in different stages and forms of insanity, as well as of different classes of society it may be, can but retard, if it does not actually prevent, recovery in many cases.

The form of insanity has a bearing upon the prognosis. Hospital statistics give a wrong impression of the outcome of the principal varieties, as it is chiefly

⁴ Dictionary Psychological Medicine, vol. ii, p. 1200.

severe cases and intractable patients who are sent to institutions for the insane. For example, there were admitted to the Massachusetts hospitals in ten years ending January, 1896, 3,354 cases of acute mania, of which 1,468 cases recovered; also 2,116 cases of acute melancholia, of which 665 cases recovered. From this table it would appear that melancholic patients were considerably less numerous than the maniacal, and that recovery was less frequent in that class; whereas melancholia is actually the commonest form of insanity by far, and the most curable; but, as has been said, only a comparatively small proportion of such cases is sent to the asylum.

Other acute forms which are especially apt to recover are: stuporous insanity, or so-called primary dementia, a disease which belongs exclusively to adolescence; confusional insanity; puerperal and lactational insanity; and that which follows acute physical disorders. But systematized delusional insanity which is of gradual development and is not ushered in by an emotional stage as are ordinary mania and melancholia and the other forms above mentioned, belongs to the chronic class, and is rarely curable. The secondary or terminal state: dementia, as well as recurrent and alternating insanity, are hopelessly incurable. Periodical insanity should be distinguished from simple recurrent insanity, and its prognosis is different. In character, course and severity, each attack of periodical insanity is identical with the others, while the long and fairly regular intervals of sanity which separate them show but little departure from the normal state for the greater part of the patient's life. Ordinary recurrent insanity, however, varies greatly in all these particulars; one attack may be mania, the next one or two melancholia. The length of the attack is also very variable, but grows, on the whole, shorter between each successive relapse; and the mind becomes weaker in the intervals, until terminal dementia closes the scene.

General paralysis of the insane, also known as paretic dementia, general paresis, and popularly as paresis, is, it is hardly necessary to say, a deadly malady, almost inevitably fatal. There are, to be sure, a few, very few, examples of recovery reported by competent observers; but they are not by any means incontestable, while the usual alleged cures are either due to faulty diagnosis or are the result of premature conclusions during some remission in its course. It is a frequent experience of the alienist to find favorable prognoses made in cases of general paresis by general physicians who have mistaken for ordinary insanity attacks of mania or melancholia that are really of paretic origin, and which far from being idiopathic functional psychoses, are simply symptomatic groups or syndromes occurring in the course of this grave structural disorder of the brain (general paresis). As mania, and especially melancholia, whether occurring from ordinary causes or from general paresis, are in many cases the same to all appearances, it is not surprising that such errors occur where the opportunity for observation is necessarily so limited as is the case in general practice. The incipient stage also of general paresis is sometimes thought to be neurasthenia or hypochondriasis, so closely does it simulate these disorders in many cases.

The duration of general paresis is often perplexing; and although we may safely say in the majority of cases that the end may come at any time within three

or four years from the onset of active symptoms at the farthest, according to the kind of care the patient receives, the nature of the attack, or the severity of the intercurrent affections to which it predisposes its victims, there is considerable variation in the length of its different stages, whether of remission or of progress. We are also given surprises occasionally in the way of temporary recuperative changes, both mental and physical, which are little short of startling, and which it would have seemed folly to predict. Ascher⁵ finds the *average* duration of cases of general paresis to rise in the following scale: (1) Cases characterized by excitement, (2) by depression, (3) by uniform dementia, (4) by alternate excitement and depression, (5) by apoplecticiform attacks. When frequent epileptic seizures are a marked feature from the first, there is great danger that the patient will be cut off by a series of them in the form of the epileptic status.

But it is the stage of remission in general paresis which is responsible for most of the mistakes of diagnosis and prognosis that are made in this disorder, as only the trained observer can find evidences of mental failure in many of these patients, who at this stage appear to be entirely well. That, however, an exacerbation is sure to follow sooner or later, in spite of this apparent return to health, and that only by the most careful and quiet living can it be long delayed, is the only opinion to be given that is consistent with fact. It is often months, and occasionally years, before the signs of degeneration recommence and our reiterated prognosis is finally verified.

The minor conditions of an attack of insanity and its individual symptoms often tempt us to predict the outcome; but it is a hazardous practice, akin in inaccuracy to amateur weather predictions. There are many, however, that are useful to know when properly estimated—like minor symptoms of physical disorders—as simply corroborative indications. Of this order is the important prognostic point that is furnished by the way in which an attack begins, as in general a quick onset means a fairly quick recovery; excepting of course cases of *delirium grave*, otherwise known as typho-mania and as acute delirious mania or melancholia, a form which is extremely dangerous to life, especially in old people. *Per contra*, a long antecedent period of mild mental symptoms or peculiar conduct betokens chronicity.

Another indication that is quite reliable is the familial one, that when improved nutrition keeps pace with the mental gain as evidenced by the patient's weight, the chances of recovery are good, while an improved physical condition unattended by mental improvement, or *vice versa*, is a bad omen. Marked hallucinations of hearing; the creation of new words; the adoption of a pathological language—of a peculiar costume; a tendency to self-decoration; special attitudes; hoarding, etc., mean, as a rule, incurability. Incoherence and persistent delusions without excitement are usually signs of confirmed mental weakness. Absence of the feeling of satiety, eating or drinking nauseous articles, are found almost exclusively in unfavorable cases; but a case of confusional insanity in a lady under the writer's observation in whom this latter propensity was well marked, made an excellent recovery. In continued sexual excitement recovery is rare; but the practice of masturbation, if given up, may not interfere with recovery.

⁵ Allg. Zeitschrift für Psychiatrie, Bd. xlv.

The intervals of calm and rationality which suddenly and unexpectedly occur in cases of melancholia and confusional insanity especially, are very deceptive, and often tempt one to make a prognosis of speedy recovery that is soon found to have been premature. It is only when these sudden recoveries of reason follow a period of decided gain in sleep and general health that they are permanent, as a rule. Generally speaking, the mind is speedily clouded over again, and the disease runs its course with renewed intensity. It is safe, nevertheless, to predict that *ultimate* recovery is probable in cases that are characterized by such intervals of rationality. A condition of unbroken excitement or depression, however, if of long duration, lessens the chances of cure. Temporary diminution of the excitement, with a change to a depressed mood, occurring in an attack of violent mania is thought to indicate recovery.

When hypochondriacal delusions are a marked feature of a case, the outlook is bad, especially if the subject be advanced in years. Such patients are apt to believe their throats or bowels are permanently closed. Some think that they have no "insides," that the body is transformed or is rotting, that certain parts are made of glass or metal, that they are being consumed by venereal disease, etc.

Persistent refusal of food, especially when due to hypochondriacal delusions and when prolonged, is an unfavorable sign. Recoveries do occur in such cases, as in other extreme conditions; but they are as rare as they are surprising.

The suicidal tendency is often regarded by people in general as a particularly ominous feature, whereas it is a frequent and logical manifestation of the most curable form of insanity, melancholia. The chief danger is of course to life, before proper measures for the patient's protection have been taken, after which his chance for recovery is quite as good as that of any case of melancholia without such tendencies.

"Mild" cases of melancholia, which are apt to be treated at home, are very deceptive in respect to the probability of suicide; and the more rational the patient the more crafty and deliberate he will often be in carrying out his plans. It not unfrequently happens in such cases that a desperate attempt at self-destruction is the first warning given the family or the physician of the suicidal propensity. Careful and frequent examination of the patient's line of thought will usually reveal the desire for suicide, after which it is a grave risk to attempt to give such a patient proper supervision at home. The desperate and violently determined melancholiac, whose efforts are constant and unremitting owing to the strength of the suicidal impulse and in whom there is little sign of reason, is doomed to dementia unless there be a speedy turn in the disease.

Finally, the best recoveries are seldom perfect, and a large proportion fail to recover their former mental condition in full. As it has been well put by Folsom: "There is left some change of character, no matter how slight, some moral perversion, irritability, impaired will, lessened power of self-control, diminished mental capacity—some lowering of the intellectual or moral standard, some deterioration of some kind."

As regards prognosis as to life, it may be said that, excluding the suicidally inclined in relatively few cases

is death to be feared as a direct consequence of insanity that is not organic. They are largely from one group—the delirious manias—the form of death being exhaustion from continuous intense and often febrile excitement. Death is much more likely to take place in the beginning of an attack, as that is the time of greatest violence and strain. It is then, too, that refusal of food and suicidal attempts are most common.

The difficulty here shown in making correct prognoses, together with the arbitrary time limit which prevails within which a patient shall be considered curable, have resulted in misapplication of the terms "acute" or "chronic" in insanity; and consequently the proper classification, care and treatment of such patients has been interfered with. The general physician finds, as a rule, vastly less difficulty in deciding this question at the outset than does the alienist. Chronic bodily disorders are in the main chronic from the start, so to speak, and follow a characteristic course. Chronic nephritis, for example, is comparatively seldom an extension of the acute variety, but as it is now generally recognized, exhibits a chronic character from the first. True chronic articular rheumatism which ends in arthritis deformans is only in a relatively small proportion of instances a direct sequel of an attack of acute articular rheumatism. Chronic bronchitis follows a similar course, and rarely arises from a genuine acute bronchitis. Then, also, in the cases in which a chronic condition does supervene as a direct outcome of an acute bodily disorder the transition stage often has such distinctive features that the fact of chronicity is soon recognized.

This condition of affairs is reversed in mental disease, although it, too, has many cases which can be recognized as chronic from the start. Such are imbeciles, degenerates, pure paranoiacs ("cranks") and cases of organic brain disease. But all these classes combined form only a minority of the chronic insane, while the bulk are cases of secondary dementia—of loss of mental power, varying in degree in different individuals, which is the direct outcome of an initial brain storm in the form of attacks of acute mania, melancholia, epileptic seizures, etc.

Of these patients, as a whole, we may rightly say at the beginning of their trouble that statistics show that a decided majority will become chronic lunatics; but we cannot point out the individuals who will certainly recover and those who will fail to do so, with by any means the same degree of certainty that is possible in physical disease. It is largely by looking back upon a case of insanity that we can with any certainty pronounce it acute or chronic. Moreover, the initial steps of the transition stage between acute insanity and positive dementia which forebode chronicity, are so very gradual and ill-defined that long observation is often necessary before we can say with certainty that the acute stage has passed and confirmed insanity is established. Another difference in this respect between mental and bodily disease lies in the fact that severity of symptoms in the latter is much more of a factor of the acute, as distinguished from the chronic case, than is the case in mental disorder, in which not unfrequently severe violent maniacal symptoms extend without material modification well into the chronic stage.

The expedient has therefore been resorted to of adopting an arbitrary duration-limit as the division-line

between acute and chronic cases. This method is unsatisfactory and unscientific, but the most practicable one available. By general consent, twelve months has come to be regarded as that limit, a standard based upon the average duration of recovered cases as computed from hospital statistics. This practically makes the terms "acute," "curable" and "recent" synonymous, as distinguished from "chronic" and "incurable" insanity.

But all asylum physicians do not hold the same opinion, some placing the limit as low as six months for curable cases. There is consequently a wide variation occasionally met with when an estimate is to be made of the number of acute and chronic cases in a given collection of insane persons. For example, in reply to a recent inquiry, made with reference to a possible separate provision for the acute insane of the city of Boston, it was found that of 1,170, the entire number of insane patients of all classes supported by that city at her own institutions and at the lunatic hospitals of the State,⁷ but 30, or 2.5 per cent., were of the acute class. This is at variance with the usual rough estimate or guess, of about six or seven per cent., which is none too large an estimate, as is indicated by the fact that the proportion of all the acute cases (mania, melancholia, dementia) to the entire number of patients of all classes remaining in all the State hospitals for insane of Pennsylvania at the end of the years 1890, '91, '92, '93, '94 and '95, ranged from 6.8 per cent. to 12.3 per cent., in an average of 6,207 patients.⁸ Also, of 62,431, the entire number of lunatics remaining in 1890⁹ in all the English asylums, 4,070, or 6.5 per cent., were reported as presumably curable.

Even the duration-limit of a year is too low, and works harm. It is scientifically inaccurate on its face, from the fact that the duration of a person's insanity is almost invariably understated by relatives. But even accepting twelve months as the correct average duration, quite a large number recover in a greater length of time. From the table in twenty-five annual reports since 1891, of five Massachusetts lunatic hospitals, which gives the whole duration of mental disease (exclusive of previous attacks) in the recovered cases, it appears, that, of 1,469 recoveries of known duration, *twenty-one per cent.* occurred after a duration of more than one year and (for the most part) under three years.

This artificial standard of duration, therefore, cannot fail to frequently consign curable cases to the limbo of the chronic class, and thus deprive them of the special care and attention which they demand and which may be essential for recovery. Patients who are thus prematurely labelled "chronic" are often removed from the State Hospitals, with all the advantages there to be had in the way of nursing and skilled medical attendance and supervision, to the town almshouse where they have little or no care, if they are not actually neglected or abused. In private cases also, by reason of the general acceptance of this standard as the limit of the acute condition, changes of treatment are often precipitated which are preju-

dicial to the best interests of patients. It often happens that a patient who is being treated privately away from home is prematurely pronounced a chronic case and hopelessly insane, when a little longer delay might have resulted in cure, and spared him the stigma which unfortunately and absurdly attaches to those who have been committed to an institution. Finally, it is not improbable that too rigid adherence to the twelve-month duration-limit is in a measure responsible for the lack of that great desideratum: separate hospital accommodation for the acute cases, by reason of the fact that it is thus made to appear that too small a proportion of patients would be available to make special and separate construction advisable.

Is it not, then, far more humane to take the small risk of treating a few chronic cases as though they were acute and curable by including in the "acute" category all whose insanity has had a duration of at least one and a half years, than to deprive a fairly large number of curable cases of the benefit of special care and treatment?

Clinical Department.

A HOMICIDAL DEATH FROM SULPHATE OF STRYCHNINE.

BY EDWIN J. BARTLETT, M.D., HANOVER, N. H.

On the 9th of March, 1895, John E. Holloway, of Glover, Vt., was found dead in one of the out-buildings of a dwelling-house in which a dance was going on. The circumstances aroused suspicion of poison; analysis disclosed strychnine. Mrs. Holloway and one William Chase were tried at Newport in the fall of 1895 and the winter of 1896. Mrs. Holloway was acquitted, and Chase was convicted.

Though many desirable details failed to come to light, there are some matters of interest in the case.

The poison was administered in alcohol. Near the scene of the crime a pint whiskey-flask was picked up; there were others, but this one contained one teaspoonful of dilute alcohol and three grains of undissolved crystals of strychnine sulphate. The alcohol when examined by the chemist held 15.2 milligrammes in one centimetre, or about one grain in a teaspoonful. Experiments in the laboratory to gain some idea of the rapidity with which solution could have been effected showed with no shaking (except momentary stirring at the end of the period to secure a uniform sample) 4.5 milligrammes per centimetre, or one grain in four teaspoonfuls, were in solution in fifteen minutes. This and several other experiments proved that there could have been no difficulty in dissolving an ample dose between drinks.

The clinical history is incomplete; the poisoning, sickness and death were all between one and three o'clock in the morning, but how much within those limits cannot be stated with any certainty. It is a reasonable conjecture that the case did not occupy more than three-quarters of an hour from beginning to end. Holloway was seen among the guests who were eating supper between twelve and one. He was seen outside the house in good condition about one. Between one and two he was sitting upon the stairs in the out-building "very sick to his stomach." He talked intelligently, suggested a doctor, then advised waiting, as he might soon feel better. This occupied

⁷ Austin and Pierce Farms in Boston, the State Lunatic Hospitals at Northampton, Worcester, Taunton, Danvers and Westboro, the Worcester Asylum for Chronic Insane and the State Almshouse at Tewksbury. No criminal insane, imbeciles or feeble-minded are included.

⁸ Reports of Committee on Lunacy, of the Board of Lunacy and Charity of the State of Pennsylvania.

⁹ Report of Commissioners in Lunacy, of England.

"about twenty minutes"; suddenly "he fell right back, kicked a little and stopped breathing." Apparently death was caused by the effect of the first convulsion upon the muscles of respiration.

The interval between the time of the death and three o'clock is not satisfactorily accounted for.

The first witness as to post-mortem condition who was entirely clear of any motives for reserve saw the body about three o'clock; the head was on the stairs supported by a butter-tub cover, and the heels were on the floor; the body was arched and rigid as iron, the arms were rigid and extended, the hands cold and clenched and the facial muscles contracted to a grin. When the physicians examined the body at two o'clock in the afternoon, one of them passed his hand between the arched back and any possible support; it rested entirely upon the heels and the head, and when they lifted it it stood upright with a little balancing. An emission of semen had taken place.

The autopsy disclosed no marks of violence. The lungs were congested. The heart contained moderate clots. A tumor, the size of a walnut, was found on the upper surface of the brain, just beneath the dura mater, near the longitudinal fissure, and about midway from before backwards. (This tumor was urged as a cause of death by the defence.) The stomach and heart, in separate jars, were delivered to the chemist for analysis. The interior of the stomach was pinkish, smooth, and normal to inspection. Its contents were ten centimetres (one-third ounce) of colorless, viscid fluid of an alcoholic odor, and two pieces of apple, one of which contained part of the core; no particles of food or other solid matter were present. It was in evidence that the deceased ate supper between twelve and one o'clock; there was, however, no history or sign of vomiting, and no one was able to tell what he ate.

The strychnine obtained was white and imperfectly crystalline; the fractions actually weighed amounted to 3.8 milligrammes of the alkaloid, giving a total of 11.6 milligrammes (two-elevenths of a grain) in the stomach contents. The taste, physical properties, chemical reactions and physiological action were completely identifying. The color reactions were strong and satisfactory with 1.0075 milligrammes (about $\frac{1}{15000}$ of a grain) of the residue. A frog weighing five grammes given by the stomach .045 grammes ($\frac{1}{15000}$ of a grain) showed muscular twitching in ten minutes, followed at once by distinct but not strong spasms for ten minutes, at the end of which period he was apparently dead; another frog weighing fifteen grammes was given the diluted remnant of the first frog's dose — certainly not more than $\frac{1}{15000}$ grain. In five minutes there were indications of the action of the poison; and in twenty minutes exceedingly powerful tetanic convulsions; their onset was accompanied with a croaking sound, and at their maximum the frog was like a tensely strung bow. After twenty-eight hours, during which the least jar or touch or breath was the occasion of a convulsion, the frog recovered.

Later, four and one-half months after death, an attempt was made to recover absorbed strychnine from the heart, which was then in a putrid condition. Forty-two centimetres of fluid were drained from it and worked through, chloroform being used as the final extractive. Thirty drops of the chloroform, evaporated in small space, left a decidedly bitter residue;

this was repeated three times. The fading purple reactions, distinct though fleeting, were obtained from evaporation of four drops, and upward, of chloroform in the same spot, but not from the evaporation of one, two or three drops. This was repeated eight times. One-third of the remaining material, after evaporation, was given to each of two frogs weighing four and five grammes; in fifteen and in eighteen minutes the frogs manifested discomfort and loss of muscular control — the hind legs tended to straighten out; but there were no convulsions. In the course of an hour and a half the frogs resumed their usual condition. The next day the same frogs were taken: to one was given all that was left of the material, and to the other nothing; the dosed frog acted as on the previous day, while the other remained as usual. At the trial no stress was laid upon these results from the heart; the facts were stated with the voluntary comment, that by themselves they were not conclusive of the presence of strychnine. On further consideration, they seem, though tenuous and difficult to maintain, to justify a more positive statement.

The carefully conducted trials of this case, though affording nothing of special importance to the medical or chemical witness, furnished a rather striking combination of what may be styled accidents of the law. At the close of the first trial, after a verdict had been rendered convicting one respondent and acquitting the other, it was brought to light that a jurymen had been disqualified from the outset; the acquitted respondent was released, the convicted one was granted a new trial, and the jurymen was convicted of perjury. It was thus made practicable — though it did not happen — for the released respondent of the earlier trial to take, as witness in the later, entire responsibility for the crime without legal penalty.

At the second trial, the jury, at first unable to agree, finally brought in the verdict of manslaughter.

An exception carried to the Supreme Court established as the law of evidence in Vermont, that "adulterous relations with wife may be shown as motive for murder of husband."

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

JAMES G. MUMFORD, SECRETARY.

REGULAR meeting Monday, February 8, 1897, Dr. A. L. MASON in the chair.

DR. CHARLES H. WILLIAMS read a paper entitled, STANDARDS OF FORM AND COLOR-VISION IN RAILWAY SERVICE.¹

DR. B. JOY JEFFRIES: The paper is interesting to me because just twenty years ago next month I first brought the question of defective form and color sense before the public. I had been at work upon it a year or two before, and then insisted on the necessity of having definite standards fixed, to be carried out by competent experts, both on the railroads, in the merchant marine and in the army and navy, and also the necessity of an international commission to settle on such standards and the carrying out of them; therefore, I entirely agree with all that Dr. Williams said

¹ See page 561 of the Journal.

on these points. There are one or two other points I will speak of.

In using Donders's apparatus, I find it convenient to be able to add different degrees of the London smoked-glass, and have so arranged my apparatus. Then a man looks at one color, and you add one of these, and the change in amount of light will make him see and say it is another color. I have always avoided asking whether it is red or green, simply saying *safety or danger, port or starboard*. As to the Holmgren test, of course I have had a good deal of experience, having made some 35,000 examinations, and therefore perhaps it is hardly fair to ask the gentlemen who start in with it to realize its value at once, or put themselves in the same position that I am from my experience with it. I should rather decide upon whether to drop a man out or take a man on by Holmgren's test than by any other one. I feel that when you have a proper set of worsteds, experience tells you what the extent of the trouble is very well indeed. The central scotoma in the tobacco case of Dr. Williams I should have supposed would have been noticed by the failure of form-sense that goes with it, but in general the use of Holmgren's test has been shown to be very reliable, and that is the report of the international conference that took place in Amsterdam in 1895. At this conference all interested desired to have better methods of measuring the amount of the color-sense, so that we could establish a standard. At present I would rather take a good set of worsteds and decide by Holmgren's method whether a man has such color-sense as he ought for his position. I consider, the less his color-blindness the more dangerous the man really is, since he is more apt to escape detection and obtain a certificate of competency.

Of course, to have standards and proper testing is very nice; but you can't get these universally applied. If on the Burlington System Dr. Williams refused men, they naturally went to the next road. When you ask the railroads to do anything which interferes with the patronage of the officials, or interferes with the men, they readily get excited. Their brotherhoods are by interested people induced to make trouble, and the railroad officials are therefore only too willing to accede, and not have anything done they can avoid. A law was passed, yet you will find the test to-day here in Massachusetts made by a master-mechanic or anybody else holding up a flag and asking the employee what the color is. Such a law is not carried out any more than the prohibition of Sunday liquor-selling. Even the Sunday illustrated newspaper has given pictures of such a test in decision of it. It is easy to talk smoothly, and make the people have an idea that men are examined and the incompetent ones thrown out; but there is nothing of the kind done.

To accomplish this, namely, the establishment of proper standards and their application by those only who are competent to apply them, is one of the objects of the international conference which is to meet again in Brussels next September. The medical men connected with the railroads and with the army and navy are going to meet. It is a conference of hygiene, but incidentally comes in the examination of men for the army and navy and merchant marine. We have the reports and opinions of what was done in Europe by gentlemen of honest intentions, but they are having as hard a fight there as I am here. Hollaud, thanks to

Professor Donders, is the only country where the work is properly done. It would have been carried out in Russia also, but for the lack of ophthalmic surgeons to enable them to have such examinations made. The surgeons of the roads do not have as much success as the special ophthalmic surgeons.

In Connecticut they had legal standards in conformity with those recommended by the highest European and English experts; but politics came in. The railroad vote was bid for by both parties. When it was referred to the railroad committee, I went the second time before that committee, with the result of seven out of nine voting to retain it. When it came to the Senate and House of Representatives, it was swept away. Here in Massachusetts, as I have shown, what law there is amounts to nothing. Anybody can be called a "competent person," and be told to keep or turn off any employee they want to. In Ohio and Illinois it was the same. In Alabama a very perfect law was made; politics came in, and it was swept away. That is all that we do with standards and proper expert testing. I agree that it is most desirable to have them, and that they should be employed; but it is a Utopian idea to believe that they are or will be employed. If we free Massachusetts from those who are color-blind and have defective vision, they are merely pushed off into other States around us. That is my position in it, and I have been in it for twenty years. I wish I could make a better report, but I cannot. But I believe that it is only a question of time; for our communities are learning the danger from defective vision and color-blindness, and will finally demand the remedy.

DR. HAY: I know very little practically about this subject. I was much pleased with this paper, and should be glad to see it printed, for I think it would give a good deal of information to oculists and surgeons generally as to what the standards are.

DR. WADSWORTH: I have very little to say. I agree with the previous speakers as to what is needed. As an illustration of the imperfect way in which some examinations are now made I may say that last spring one of the minor officials of a large railroad running out of Boston asked me to examine for color-blindness some half-dozen of their men who were to be entrusted with the examination of the others. He said it was only by his insistence that any such step as that had been taken. It had been proposed to have these men make the examination without any idea of whether they were competent or not, whether they were themselves color-blind or not. One of them proved to be to a considerable extent color-blind. Within a few days I have seen a conductor who only has one eye and only about one-fourth vision in that one.

DR. JEFFRIES: A man came to me—a master-mechanic on the New York and New England Railroad—whose business it was to examine the men. I found that he was completely color-blind. He told me he often sat down by the tracks and watched the changing lights with his boy, and that he never could distinguish the colored lights or notice the change, whilst the lad could do so readily.

DR. STANDISH: I think these examinations ought to be made earlier. A few years ago a man was allowed to get on an engine and run three to six years with the expectation of being engineer, and was then turned down because he was color-blind; and I think

a large part of the opposition comes from the men who are afraid of being turned off because they may be found color-blind. It seems to me that if an examination was made of every man who went on the road, from section-hand up, there would be very much less opposition to the law. In the English marine a man may go to sea at twenty without any examination; yet when he comes up for mate's certificate at thirty-five, be thrown down because he is color-blind.

DR. JEFFRIES: There is no examination under our government for mates or masters. The master or mate of a vessel may be half-blind, or color-blind. The only examination is of pilots. Every possible effort has been made to prevent such examinations being properly carried out, as with the railroads. The marine-hospital surgeons are directed to make them by Holmgren's test. But they succeed in detecting the color-blind pilots, hence in the interest of the latter, the rule last published says that if the pilot is one hundred miles from a United States marine-hospital surgeon, he can apply to "any respectable physician," and his certificate suffices. But a Druid Medical College graduate is legally a respectable physician.

MR. FRENCH: I had not expected to be called upon. I came to listen, at the invitation of Dr. Williams. I have had considerable experience in this matter, and possibly, as being a practical railroad man, it may be of some interest to you. I have been all my life on the railroad. Color-blindness and deficiencies of sight were not brought forcibly to our attention until about 1881, when a law was passed requiring an examination for colors and sight. The law was passed, and we prepared to comply with the law. Dr. Jeffries, I think, thought the examination should be made wholly by medical experts. Some of the roads, like the Pennsylvania, thought it was impracticable and unnecessary to have them all made by a medical expert, and that a layman in the employ of the railroad might be selected and qualified to make them and ascertain those who were deficient, and where there was any doubt or where they did not come up to a certain standard to be prescribed by a competent oculist the case should be referred to the expert. I am now with the New Haven Road; but then we were the Old Colony Road, and I was Superintendent of its Central Division. Our President, Mr. C. F. Choate, and General Manager, the late Mr. J. R. Kendrick, desired me to make the examination of the whole Old Colony Road. I therefore received instructions from a competent oculist (the late Dr. H. W. Williams), and was declared qualified to make the examinations and ascertain those deficient in the employ of our road; and I made them in an honest manner. The law was strictly complied with, and there was no favoritism whatever. I went through the whole list, and had a good many hard cases to deal with.

This was the first examination on the road, and there were many hardships. It was a hardship to the individual who failed to pass; but it would have been a greater hardship to the railroad to have had to continue an employee who proved deficient, and the result was beneficial to the railroad and also to the public. I examined some over three thousand cases, and found about four in a hundred deficient in some way. The instructions of my superior officers were to report to Dr. Williams all cases that did not come up to the specified standard; and we gave every employee who

failed to pass, the opportunity of an examination by Dr. Williams if he wished. I gave this opportunity to every one but two. Two conductors could not see the large C on the card; and Dr. Williams said they would be dangerous as conductors, as a conductor wants a field of vision to see whether any one is getting on or off the length of his train, and that it was useless to send them. In some cases, where I was in doubt and did not understand the case, Dr. Williams made examination and passed them; in other cases his examination failed to pass them. We went through our list in as perfect a manner as possible, and if our old employees were found lacking and unfit for their positions we found other positions for which they were still competent, if possible, and nearly all were provided for in that way.

We took for examination the enginemen, firemen, conductors, stationmen, switchmen, yard-masters and yard-crews, drawtenders, towermen, section-foremen, crossing-men — every one who had to do with colors or signals. With our enginemen, firemen and trainmen, we did not require normal vision in both eyes for the old employees, but in hiring new men we required them to come up to the fullest standard. We did not hire men for these positions who fell short, because we wished to start right and be sure that we would obtain from them a reasonable term of service before deterioration set in; and in the case of firemen, these men fire five or six years, and, if competent, became enginemen, and they should start as enginemen as nearly as possible with normal vision. With the men in our employ at the time of examination, we allowed some latitude, as prescribed by Dr. Williams; and those who did not come up to the full standard we have re-examined from time to time. Lists were made of those approaching the danger line, and many of them have since been rejected and put in other positions. Some of the enginemen went into the shop to work, etc.

We have kept up our examination since then. The re-examination has not been so fully performed as Dr. Jeffries, Dr. Williams or myself would be glad to see. No relatives are passed on account of their being relatives. When the road increased in size it was divisioned off, and some of the other superintendents were examined and passed as qualified to make these examinations. Applicants who did not come up to the standard were at once rejected. We made a difference in the certificates issued; and, in some cases, and for certain positions, glasses were allowed. In only one instance were glasses allowed an engineman, and this by the oculist's advice. Glasses may make a station-agent perfectly competent for his position. Crossing-men may be located in positions where the view is limited and where hearing is more to be depended upon than sight, and therefore glasses might be allowable. In some other positions glasses have been allowed; but in each case we made a qualified certificate, specifying the particular position or location the man was passed for.

DR. JEFFRIES: I want to say most explicitly that the gentlemen on the other side of the water who have given the best attention practically and scientifically to this subject say these tests should be carried out only by competent experts, and the best men are ophthalmic surgeons. I cannot take as being a competent test what Mr. French did, or as any proof that that road is safe from the color-blind or those having

defect of vision. The test as applied by Dr. Thomson is not a true Holmgren test for color-blindness; and therefore I do not receive its testimony here. The examiners may have been perfectly fair and honest and may have done what they thought all right, as they were told they were competent. The thing should not have been done that way. That there were only four per cent. of the color-blind and those having defects of vision among his men, proves to me very conclusively that the tests were not rigid enough or were not carried out correctly. Even as carried out on the Pennsylvania Railroad, four per cent. of color-blind were found, and ten per cent. with too defective vision for their positions.

DR. WILLIAMS: I want to make just one remark in closing. I think we are all indebted to Dr. Jeffries for the pioneer work which he has done in this direction, and work of such character that it has stood the test of time. My reason for presenting the paper at this time is that we must continue to call attention to the need of better methods of examination and more uniform standards. From my own experience I know that there is more honest effort on the part of railroad officials to improve their service than ever before, and I believe much can be accomplished by having such tests made. I think the only way to do it is to keep urging the matter, and to show the necessity of having careful examinations and sufficiently high standards.

AMERICAN GYNECOLOGICAL SOCIETY.

TWENTY-SECOND ANNUAL MEETING, WASHINGTON,
MAY 4, 5, 6, 1897.

(Concluded from No. 22, p. 549.)

THIRD DAY. — THURSDAY.

DR. THOMAS ADDIS EMMET, of New York, read a paper entitled,

WHEN TO AMPUTATE IN PREFERENCE TO THE USUAL OPERATION FOR LACERATIONS OF THE CERVIX UTERI.

Stress was laid upon the fact that the operation as described in this paper is not intended to take the place of trachelorrhaphy, but is to be employed in those cases in which, by reason of the impaired condition of the tissues, depth and extent of the laceration, or excessive scar tissue in the angle thereof, it is impossible to repair the cervix by the usual method. The operation described consisted of making an excavation in the cervix with curved scissors, removing all unhealthy tissue, and uniting the remaining flaps to the lining of the uterine canal with silver sutures. Strict antiseptic precautions should be observed, and care taken to secure patency of the uterine canal.

DR. H. T. HANKS, of New York, was glad to hear the indications for amputation so clearly defined, because some operators have of late been advocating the operation in place of the bilateral operation.

DR. PAUL F. MUNDÉ, of New York, agreed with the author that it is often impossible to get good results without removing some of the cervical tissue. In cases of elongated cervixes, he amputates the cervix with a knife and, if the uterus is hypertrophied and prolapsed, narrows the vagina and performs Alexander's operation.

DR. J. RIDDLE GOFFE, of New York, took exception to the term "amputation of the cervix," because it might give rise to the impression that the operation is done with the *ecraseur*. He thought that in nearly all cases a good result would follow the Emmet operation for repair of the cervix, and was of the opinion that removal of the cervix destroys the equilibrium of the uterus.

DR. A. PALMER DUDLEY, of New York, was in favor of amputation of the cervix, because in many cases no other operation is applicable.

DR. BACHE McE. EMMET, of New York, considered the operation a good one in such cases as could not be treated by trachelorrhaphy.

DR. E. C. DUDLEY, of Chicago, said he had employed a modification of the Schroeder operation in many cases where the scar tissue in the angle of the wound was inaccessible.

DR. THOMAS ADDIS EMMET, in closing, said the Schroeder operation is identical with the one advocated in the paper, which the speaker has performed since 1866. It was devised by Dr. Sims, but was not successfully performed by him on account of oozing of blood through the flaps and the formation of abscess.

DR. A. LAPHORN SMITH, of Montreal, read a paper entitled,

RESULT OF TWO HUNDRED OPERATIONS FOR THE CURE OF RETRO-DISPLACEMENTS OF THE UTERUS.

Dr. Smith said that ventral fixation, which is considered unjustifiable by many surgeons on account of the dangers attending it, notably obstruction of the bowel, is indicated in those cases where retro-displacement of the uterus is complicated by adhesions. Alexander's operation should be employed in all cases where there are no adhesions, but a simple falling back of the uterus and appendages. The operation is contraindicated when the uterus, after having been brought up to the symphysis pubis, immediately springs back to its former position. The author described a method by which the operation can be performed in a minute or a minute and a half, and said there is no difficulty in finding the round ligaments if this method be employed. The operation is without primary mortality and has none of the disadvantages of ventral fixation.

DR. M. R. MANN, of Buffalo, read a paper entitled,

INTRA-ABDOMINAL SHORTENING OF THE ROUND LIGAMENTS FOR POSTERIOR DISPLACEMENTS OF THE UTERUS.

He gave a report of 58 cases treated by a new method, consisting of shortening the round ligaments by doubling them on themselves in three equal lengths, and stitching them together after making a median abdominal incision.

DR. EDWARD REYNOLDS, of Boston, read a paper entitled,

A PRELIMINARY REPORT ON A NEW METHOD OF VAGINAL FIXATION.

After describing the forces which determine the normal position of the uterus and showing, by means of drawings, how a faulty attachment anteriorly or posteriorly would throw the uterus backward or forward, the author described an operation designed to correct a too low anterior attachment. An anterior vaginal incision, similar to that made in hysterectomy,

is made, and the bladder separated up to the level of the internal os; the uterus is then put in position, and the point at which the bladder separates from the anterior wall is determined by a sound introduced into the bladder; a silver-wire suture in a silk carrier is introduced in the vaginal wall at a point in front of the separation from the bladder, passing obliquely through the tissues and emerging on the cut surface below the junction of the vaginal wall with the bladder, and then drawn through the cervix at the level of the internal os and brought out through the anterior vaginal wall at a similar point on the opposite side. A second suture is placed as near the first as is convenient, care being taken that the uterus is still well forward. The sutures are then twisted and turned down. As the stitches will be exposed to considerable traction, coarse wire should be used. The cut edges of the mucous membrane are then stitched together with fine catgut in such a way as not to increase the tension on the deep sutures.

DR. J. RIDDLE GOFFE, of New York, read a paper entitled,

SHORTENING THE ROUND LIGAMENTS THROUGH THE ANTERIOR VAGINAL FORNIX FOR POSTERIOR DISPLACEMENTS OF THE UTERUS.

The author has employed the method in eight cases with good results, and gave the following description of the technique of the operation: After the uterus is drawn well down to the vaginal outlet, a cross-section is made at the utero-vaginal junction and the vaginal tissues dissected off the bladder down to the peritoneal reflection; the central point of this incision is then caught up and the anterior vaginal wall drawn taut; a longitudinal incision is made down to the neck of the bladder, and the tissues from the urethra to the cross-section are separated by blunt dissection for half an inch on both sides; the peritoneum is then opened, and the finger passed in and hooked over the fundus of the uterus, and the latter brought into the vagina. Any adhesions which may exist are now broken up, and the appendages inspected and removed if necessary. The round ligament of first one side and then the other is picked up with the fingers, the sheath opened with an aneurism needle, the ligament drawn up two or two and a half inches, doubled upon itself, and stitched with two or three fine sutures; the uterus is then replaced, a little gauze is introduced between it and the bladder, and the longitudinal incision closed with a running catgut suture.

DR. PAUL F. MUNDÉ, of New York, was much gratified to see how generally Alexander's operation has been accepted, because he was the first to perform it in this country. The operation is indicated, and results in a permanent cure, in all cases where the retro-displaced uterus is movable and the appendages not diseased.

DR. BEVERLY McMONAGLE, of San Francisco, referred to the frequent occurrence of suppuration following Alexander's operation, and is in favor of opening the abdomen in these cases and suspending the uterus after Kelley's method. He is opposed to ventral fixation on the ground that it interferes with pregnancy, and said that patients upon whom vaginal fixation has been performed often complain of numbness and pain in the vagina.

DR. A. PALMER DUDLEY, of New York, said he had recently lost a patient from obstruction of the

bowel following ventral fixation and would never perform the operation again. He also referred to the pain caused by the uterus rising in the pelvis when pregnancy occurred after the operation. He is in favor of Alexander's operation in cases where a diagnosis of perfect appendages can be made.

DR. CHARLES P. NOBLE, of Philadelphia, cited the case of a woman who had died in labor as a result of ventral fixation, and is opposed to the operation in child-bearing women because it so often interferes with pregnancy. Suspension of the uterus is without this disadvantage, and is to be preferred. He has employed Alexander's operation in suitable cases and with fairly good results. If the wound is closed by the Bassini method, there is but little danger of hernia.

DR. H. J. GARRIGUES, of New York, said he had performed Alexander's operation, combined with removal of the appendages, in several cases with good results, but does not think the operation is of any value if the uterus is hypertrophied and prolapsed. Amputation of the cervix is indicated in such cases to induce involution of the organ and reduce its weight.

DR. E. E. MONTGOMERY, of Philadelphia, read a paper entitled,

PELVIC BLOOD COLLECTIONS, AND THEIR TREATMENT BY VAGINAL INCISION.

Intra-peritoneal and extra-peritoneal hemorrhage, although due to many causes, most frequently occurred as a result of rupture of an ectopic pregnancy, and often is so rapid as to cause speedy death. Hematocele from other causes often remains encysted for a long time without giving trouble, or may become absorbed. In cases where hemorrhage is recent and is believed to have ceased, no attempt at evacuation should be made when the case is first seen, for fear of dislodging a clot and causing a recurrence of the bleeding. In all other cases the blood-collection should be evacuated by vaginal incision, the cavity irrigated with normal salt solution and packed with sterile gauze.

DR. HARRIS mentioned two cases of hematocele which had come under his observation. In the first instance hemorrhage had resulted from torsion of the pedicle of an ovarian cyst. The second case was a woman who had recently been confined. The labor was normal, but soon after an abscess appeared in the vagina which discharged spontaneously. A tumor remained, which the speaker incised, evacuating a large quantity of pure blood.

DR. BACHE McE. EMMET, of New York, agreed with the author that vaginal incision and evacuation is the proper treatment in cases of pelvic blood-collections, and advised exploration of the pelvic cavity to determine, if possible, the source of the hemorrhage.

DR. E. W. CUSHING, of Boston, then read a paper entitled,

SOCIOLOGICAL ASPECTS OF GONORRHEA.

The author dwelt upon the importance of the remote effects of gonorrhea on the human race, and said it was the duty of the physician to endeavor to check the spread of the disease by instructing his patients in regard to its frightful consequences. Legal recognition of the social evil has had but little effect in those countries where it is practised, and the author did not think the remedy lay in this direction.

DR. H. J. GARRIGUES, of New York, spoke of the importance of protecting the future wife and children

by teaching men to avoid the disease. If they will not be chaste, they should at least take precautions against contracting the disease. The speaker was in favor of regulation of the social evil by law, and in this way restricting it.

PROFESSOR HUTCHINSON, of Buffalo, said he had made a study of the subject, and his views were the same as those of the author. He laid stress on the sterility which follows gonorrhea in men as well as in women. He agreed with the author that legal enactment would have no effect in controlling the spread of the disease.

DR. ASHTON, of Philadelphia, pointed out the fact that the disease is generally spread by secret prostitutes, and it is impossible to reach these by legislation. He was also of the opinion that legal recognition of the social evil is demoralizing to a community and lowers its tone. The physician should tell men the terrible results of the disease, and appeal to their self-interest in order to make them avoid it.

DR. A. PALMER DUDLEY, of New York, said that the remote effects of gonorrhea cannot be over-estimated, and that a diagnosis of the disease can always be made from the pathognomonic signs given in this paper. The disease should be treated by heroic measures. He also referred to the value of microscopical examination of discharges and pus, and said he had recently removed a quantity of pus from the pelvis of a young woman which was found to contain gonococci. The husband confessed to having had several attacks of gonorrhea.

The PRESIDENT then introduced the newly-elected president, DR. PAUL F. MENDÉ, of New York.

Recent Literature.

Anomalies and Curiosities of Medicine. Being an encyclopedic collection of rare and extraordinary cases, and of the most striking instances of abnormality in all branches of medicine and surgery, derived from an exhaustive research of medical literature from its origin to the present day, abstracted, classified, annotated and indexed. By GEORGE M. GOULD, A.M., M.D., and WALTER L. PYLE, A.M., M.D. Imperial octavo, 968 pages, with 295 illustrations in the text, and 12 half-tone and colored plates. Philadelphia: W. B. Saunders, 1897. Sold only by subscription.

In view of the natural interest taken by men of science in the rare and curious manifestations of nature's handiwork, an interest of which the general eagerness on the part of physicians both to publish and read descriptions of rare and unique cases is an indication, the authors of this book have been led to notice and endeavor to supply the need of a general work, devoted to the collection and presentation in compact form for reference of the more interesting anomalies and curiosities of human development. The volume which they have produced is perhaps the first attempt which has been made to classify and epitomize the curious and interesting literature of anomalies, monstrosities and the like.

The result of their work is a handsome, well-illustrated work of nearly a thousand pages, in which the seeker after the quaint and unusual in medicine

will find his curiosity gratified, and any man who has had a "unique" case will probably find another which equals or surpasses his own.

A Practical Treatise on Diseases of the Skin. For the Use of Students and Practitioners. By JAMES NEVINS HYDE, M.D., and FRANK H. MONTGOMERY, M.D. Illustrated with 110 engravings and 12 plates in colors and monochrome. Fourth and revised edition. Philadelphia and New York: Lea Bros. & Co. 1897.

The fact that the fourth edition of this well-known work follows its predecessor in the short time of four years testifies to the success that it has met with at the hands of the medical public. The present edition has been carefully enlarged and many new chapters added. Numerous diseases that have only of late been made the subject of accurate study by dermatologists are here introduced for the first time. Three new plates and five new engravings have been added. It may be fairly considered the best modern treatise on dermatology that has been completed by an American writer.

Essentials of Gynecology. By DR. OSCAR SCHAEFFER. Vol. V, Wood's Medical Hand Atlases. New York: Wm. Wood & Co. 1897.

In this book the author sets before himself the somewhat unique object of presenting to the profession a collection of plates which shall be sufficiently accurate to convey a correct idea of the appearance of the common pathological lesions to those who have never seen the lesion itself. These are added to and explained by a large number of colored and uncolored schematic drawings. The plates throughout are exceptionally fine, reflecting the greatest credit on the industry and accuracy of the author, and the enterprise of the publishers. For the sake of these plates, the book ought to be in every medical library, and will be of considerable value to students. The book differs from most atlases in being of a handy and convenient size.

It is surprising, in so long a series of pictures, to see the subject of salpingitis disposed of in one schematic drawing and a few reproductions of microscopical sections; but when one finds that the author treats the subject of adherent retroversion with scarcely a mention of any possible implication of the tubes therein, and advocates its treatment by the forcible breaking up of these adhesions, one understands better his reasons for this omission, which must nevertheless diminish the value of the book from what it might have been.

The book is divided into two parts: the first consisting of the plates with explanatory text; the second, of a short treatise or text-book. The latter is excellent in so far as the chapters and sections upon malformations and injuries go, the special value of these chapters lying in the extremely extensive enumeration of possible abnormalities, and in the excellent little figures with which they are illustrated. The remainder of the book is little more than an outlined enumeration of certain important points in gynecology. These are hardly complete enough to be of real value to the expert, and are so brief and concentrated that they would be unintelligible to a beginner. The value of the book lies, as has been said, in its plates, and these are most excellent.

Lectures on Renal and Urinary Diseases. By ROBERT SAUNDBY, M.D. (Edin.), etc. With numerous illustrations. Second Edition. Philadelphia: W. B. Saunders. 1897.

Dr. Saundby is professor of medicine in Mason College, Birmingham, England. The first edition of these lectures was published in 1889. A fourth section, on Miscellaneous Affections of the Kidney, has been added to the present volume; the first section treats of Bright's Disease, the second of the Urine and its Clinical Examination, the third of Diabetes.

The book is a small octavo of 420 pages, with a fairly good index of subjects and names.

The Surgery of the Chest. By STEPHEN PAGET, M.A. (Oxon). F.R.C.S., Surgeon to the West London Hospital and to the Metropolitan Hospital. Illustrated. New York: E. B. Treat. Bristol, England: John Wright & Co. Montreal: J. Hood Company. 1897.

Dr. Stephen Paget has written a book in which he has tried to put together the surgery of the chest following injury and in disease. It is divided into two parts: Part I, Injuries of the Chest; Part II, Diseases of the Chest. There are two appendices, one being M. Reclus's Address at the French Surgical Congress, the other being on Bulau's Treatment of Empyema by Continuous Syphon-Drainage.

The author has taken up the subjects in an interesting way and illustrates each subject by recording cases. His work is attractively written, but lacks a judicial spirit. It is a book that the surgeon will turn to for unique cases, but not one which will be useful as a guide to a plan of treatment for an individual injury or disease.

The printing is poor, the illustrations are indifferent, and as a piece of book-making it is not satisfactory.

A Guide to the Clinical Examination of the Blood for Diagnostic Purposes. By RICHARD C. CABOT, M.D. With colored plates and engravings. New York: William Wood & Co., 1897.

This work is the first dealing exclusively with the blood to be published in English. It is entirely devoted to the clinical and practical sides of the subject, special attention being given to the application of the results of the examination of the blood to the differential diagnosis of disease. It is to be hoped that the author will later see his way clear to deal with the theoretical side of the subject also.

The work contains the most complete collection of blood examinations in any language, the majority of them being original. No one who has not done practical work in the examinations of blood can have any idea of the amount of labor which they represent.

The bibliography is most complete, and is admirably arranged. Hence the book cannot but be most useful not only to one who wishes to know at once what has been determined as to the blood in any disease but also to one who wishes to investigate the subject more carefully. In short, the work occupies a unique and extremely useful position.

The description of the technique of blood examination is altogether the best of which we know and, if carefully followed, will enable the beginner to avoid most of the pitfalls into which he is likely to stumble. We are glad to see that the author prefers the blood

counts to the hematocrit and that he emphasizes the inaccuracies of the von Fleischl hemoglobiometer, but are somewhat surprised that he mentions no method of staining beside that with Ehrlich's "triple stain."

Primary "simple anemia" is not mentioned in the classification of the anemias. We doubt if this is an improvement. The article on pernicious anemia is especially good and contains much that is original. Greater stress is laid on the importance of megaloblasts in the diagnosis of this condition, however, than seems justifiable without further verification.

The main feature of the book is the section on leucocytosis. It is very complete and contains a great many original examinations. The definition of leucocytosis is very careful and conservative and an improvement on any that we have seen. The explanation of "inflammatory leucocytosis" is also worthy of special mention. We feel, however, that the author has exaggerated the value of leucocytosis in differential diagnosis except in certain conditions.

In the article on leukemia attention is called to several points which we have not seen mentioned elsewhere, namely, the marked variation in size of myelocytes, the frequent occurrence of cells intermediate between polymorphonuclear leucocytes and myelocytes and the great number of nucleated red cells.

The blood conditions in infancy have hardly received the notice which they merit, but the difficulty of distinguishing and classifying the blood diseases of childhood is emphasized and the existence of anemia infantum — pseudo-leukemia von Jaksch — is, as we think, justly questioned.

The blood plates are exceptionally fine as regards the red corpuscles and lymphocytes, but are far from satisfactory as regards the various forms of granular leucocytes.

A Treatise on the Surgery of the Alimentary Canal, comprising the Esophagus, the Stomach, the Small and Large Intestines, and the Rectum. By A. ERNEST MAYLARD, M.B., B.S. (Lond.), Surgeon to the Victoria Infirmary, Glasgow; Examiner in Surgery to the Conjoint Board of the Royal College of Physicians and Surgeons of Edinburgh and the Faculty of Physicians and Surgeons of Glasgow; Late Examiner in Clinical Surgery to the University of Glasgow, etc. Philadelphia: P. Blakiston, Son & Co. 1896.

In this work of 698 pages the author has carefully given the anatomy, pathology, symptoms, diagnosis and treatment of essentially all the diseases of the intestinal canal. He has introduced into the text, wherever it would be of advantage, the history of some case. In this manner he brings the subject home more forcibly to the reader. The work compares very favorably with similar ones. The various operations which are advised for the intestinal tract are well set forth, but we miss an intelligent sifting of the various operations which would add greatly to the value of the book. The reader is left with the impression that any of the operations advised can be attempted, and there is no definite expression of opinion as to their relative value. This may be due to a lack of personal experience on the part of the author; but we trust that in a future edition the author will express his opinion as to the value of various methods of treatment.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JUNE 10, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

 283 WASHINGTON STREET, BOSTON, MASS.

THE FIFTIETH ANNUAL MEETING OF THE
 AMERICAN MEDICAL ASSOCIATION.

THE annual meeting of the American Medical Association at Philadelphia, which marked the fiftieth year of its life as an associated body, was a successful occasion—whether measured by the number of the members who attended, or the enthusiasm of hosts and guests. About nineteen hundred members are said to have been enrolled and about sixteen hundred to have been in actual attendance—the largest number ever gathered at any one meeting. Those in charge of the arrangements deserve much credit for their energy and activity.

Notwithstanding the vast number of titles announced, some very good papers were actually presented, read and intelligently discussed. This was especially true of the Section on General Medicine, one of the most difficult to keep within the bounds of scientific discretion. In his address as President of the Association, Dr. Senn was glowing as to the past and most sanguine as to the future. He foresees the time, before the expiration of another fifty years, when the course of search for advanced scientific medical study and training will be reversed, and will have taken its way westward from the European continent to the United States, and the membership of the Association will reach one-hundred thousand. He proffered his fellow members some wholesome advice on the subject of medical politics.

Dr. W. W. Keen delivered a scholarly and critical address on Surgery, nor did he refrain from the rôle of the prophet. He anticipated the singing of a glorious surgical *Te Deum* in 1947, when in a surgical paradise the knife will be laid aside, and by means of suitable toxins or antitoxins, drugs or other methods of treatment, inflammation will be controlled, suppuration arrested, the ravages of tuberculosis or of syphilis stayed, tumors and cancers aborted or dispersed, and human life be so prolonged that all of

the then audience will die either of accident or of old age. He paid a timely tribute to the value of animal experimentation, and in this was vigorously supported by Dr. H. C. Wood. Dr. Keen is of the belief that, "Bacteriology would not now exist as a science, nor would accurate modern surgery and a large part of modern medicine be possible, had experiments upon animals been prohibited, as some zoöphilus women who love dogs better than men and women, and even little children, desire."

The Association adopted a resolution presented by Dr. Wood, protesting against the passage by Congress of the bill now pending to regulate the practice of vivisection in the District of Columbia.

The Association was welcomed by the Mayor of the city of Philadelphia and by the Governor of the State of Pennsylvania, and was honored for a brief period on the second day by the presence of the President of the United States.

For the week preceding and following this meeting the zealous committee of arrangements arranged for clinical courses open to all physicians visiting the city, that all might have an opportunity of seeing the active clinical work of all the great teachers of Philadelphia, and be impressed with its importance as a medical centre.

Numerous luncheons and receptions were tendered by residents of Philadelphia, and the different sections all had their stated dinners on Tuesday evening.

The next place of meeting will be Denver.

CANCER OF THE PANCREAS.

CANCER of the pancreas is by no means as infrequent as the really sparse literature of this disease might lead one to suppose. The busy practitioner is continually meeting with cases of either primary or secondary carcinoma of this organ, and many obscure cases diagnosticated during life as gastro-hepatic disease are found at the autopsy to be primary cancer of the pancreas. Dr. Hale White, after looking through the records of Guy's Hospital for the twelve years 1883-1894, both inclusive, found that 6,000 post-mortem examinations had been made; of this number, there were 19 cases of primary cancer of the pancreas and 11 of secondary malignant deposits in that organ.¹ In a clinical study Segré found in 11,492 cases followed by autopsy, 132 tumors of the pancreas, of which 127 were carcinoma.² In only 12 of these cases the pancreas was alone the seat of cancer. There were in all, 627 cases of abdominal cancer.

In a memoir by Bard and Pic,³ we find that cancer of the pancreas is much more frequent in men than in women, and is for the most part prevalent between the ages of fifty-eight and seventy-four years.

Despite the relatively early monographs on cancer of the pancreas by Aucelet and Da Costa, we are in-

¹ Lancet, December 26, 1896, p. 1806.

² Sajous' Annual, 1889, C. 50.

³ Revue de Méd., April and May, 1888.

debted to Dr. Bright in 1832 for the first careful study of this disease.⁴ He first called attention to the presence of fatty matters in the stools in patients afflicted with destructive disease of the pancreas. Bright noted in many of his cases scirrhus of the head of the pancreas, a thickened, contracted and cancerous duodenum and obliteration of the common bile duct at its duodenal extremity. There were jaundice and clay-colored stools. Dr. Bright laid more stress on the presence of fatty stools as a criterion than subsequent observers have done.

Gross in the earlier as well as later editions of his "Pathological Anatomy" well describes the post-mortem appearances in cancer of the pancreas. He had observed the disease affecting the entire gland; in other cases only portions of it. The head is most frequently implicated. The disease completely destroys the glandular parenchyma. It very frequently coexists with scirrhus of the stomach, duodenum and liver. The pancreas generally becomes irregularly lobulated and enlarged. When the disease is chiefly confined to the head of the organ, it compresses the choledoch duct, causing jaundice. Encephaloid disease is exceedingly rare.

Da Costa⁵ analyzed forty cases of cancer of the pancreas. He regards as the most trustworthy symptoms: a tumor in the epigastric region; pain there or in the back, not increased by the taking of food, but usually augmented by the erect posture, progressive emaciation and debility; an appetite capricious rather than diminished; constipation, and at times, but far from invariably, fatty stools.

Bard and Pic,⁶ from careful observation of seven well-marked cases of primary cancer of the pancreas, draw the following conclusions: The patients are usually past middle life. Jaundice generally sets in gradually, occasionally suddenly, and once present, it never disappears, but increases in intensity. It is accompanied by severe digestive troubles. The gall bladder is distended, the tumor may sometimes be felt against the vertebral column in the situation of the pancreas. All the signs of biliary retention are present. Cachexia and emaciation are well marked and progress rapidly. Hemorrhages occasionally occur. The onset of the disease is frequently characterized by the sudden development of gastric disturbance with vomiting and diarrhea followed by jaundice. The liver is generally small and hard, rarely slightly enlarged, never "mammillated" as in secondary hepatic cancer. Epigastric or dorsal pain is a fairly constant symptom. The vomited matter is never bilious. The stools are often fatty. The urine is almost always albuminous, and occasionally contains sugar. The temperature is habitually subnormal. The most frequent form is epithelial cancer of the glandular type; secondary cancer-nodules generally occur in the liver, presenting the same characters. The compression of

the bile ducts sets up changes in the liver resembling biliary cirrhosis. Secondary cancer of the pancreas differs radically from primary cancer, the structure varying according to the nature of the original neoplasm.

Miralié, who published an exhaustive study of the literature of cancer of the pancreas in 1893,⁷ assigns to primary cancer two stages: a first characterized by glycosuria with symptoms of wasting diabetes and stearrhea; and a second in which there is no glycosuria, but icterus and cachexia. The glycosuria is the *diabète maigre* of the French, which however, may attend any destructive disease of the pancreas. The duration of the disease is from four to six months. As to diagnosis, no single sign or symptom is pathognomonic: epigastric pain, icterus, dilatation of the gall bladder, anorexia, cachexia and stearrhea should suggest disease of the pancreas. He found the disease twice as frequent in men as in women, and nearly always located in the head of the gland.

In Lænnec's case of primary carcinoma of the pancreas without secondary involvements, the symptoms presented were dyspepsia, anorexia, diarrhea and profound emaciation. A small, hard tumor was felt by deep pressure at the left angle of the colon. Cachexia appeared and gradually increased. Sugar was not found in the urine during life.⁸

Dr. W. Hale White⁹ in a very valuable "Clinical Lecture on Carcinoma of the Pancreas," emphasizes as diagnostic signs the wasting, rigidity of the abdominal muscles, severe deep-seated pain, and tenderness and vomiting. The rigidity of the abdominal muscles always means organic disease underneath them. It is necessary in these cases to give an anesthetic before a satisfactory examination can be made. When the pancreas is the seat of secondary deposits or there are hard growths of other organs adherent to it, the symptoms of the primary disease quite overshadow those due to the affection of the pancreas. The malignant growth is almost always scirrhus. Sometimes the fat in the stools forms a thick scum about the edges of the vessel containing the feces. Of course the treatment of this disease is purely symptomatic. But little can be hoped from hygiene, medicine or surgery. The pancreas is an organ of such importance in the human economy that the suppression of its function entails the most serious consequences to digestion and nutrition. At a recent Congress of German Surgeons, the surgery of the pancreas was discussed by Krönelin. He regarded primary cancer of the pancreas as much less frequent than secondary cancer, due (generally) to propagation of cancer of the pylorus. This carcinomatous affection is, doubtless, a contraindication to resection of the stomach. Must we also renounce extirpation of primary cancer of the pancreas? Experiments on animals have shown that the total ablation of the pancreas may be attempted with success and without any serious consequences to the general

nutrition. Unfortunately, the habitual seat of primary cancer is the head of the pancreas, in a region where the lesion of the organs in the vicinity may be speedily fatal. The diagnosis is impossible at the onset when there might be some chance of success. The symptoms indicated by the authors as characteristic are due in reality to extension of the neoplasm to the neighboring organs. The operation is then impossible. In primary cancer of the head of the pancreas our treatment can be only palliative; we aim as far as possible to remedy the consequences of the occlusion of the common bile duct by the neoplasm. On the other hand, the radical operation is perfectly indicated in carcinomata of the body or tail of the pancreas, and it has already been once performed with success.¹⁰

MEDICAL NOTES.

WEARING OF CORSETS FORBIDDEN.—The female employees of many German factories are forbidden to wear corsets during working hours.

THE DUCHESS OF TECK.—The Duchess of Teck was recently operated upon by Mr. Herbert Allingham for strangulated umbilical hernia, and is now well advanced in convalescence.

DR. SAJOUS TO RETURN TO PHILADELPHIA.—Dr. Charles E. Sajous, editor of the "Annual of the Universal Medical Sciences," has been appointed professor of laryngology and dean of the faculty of the Medico-Chirurgical College of Philadelphia, and will return from Paris to Philadelphia to take up his new duties.

A GRANDMOTHER AT TWENTY-SIX.—Dr. H. O. Hyatt reports, in the *Philadelphia Polyclinic*, the case of a girl who had an illegitimate daughter a month before her thirteenth birthday. This daughter was married at twelve years of age, and had a son when twelve years and eleven months old. She has since had seven children, is in fair health and does not look prematurely aged. She grew four inches after the birth of her first child.

TWO VERMIFORM APPENDICES FOUND.—The following telegraphic report recently appeared in the daily papers:

New York, June 3d.—Coroner's physician Hanlon, in making an autopsy on the body of James Malone, who was found dead in the hallway of his residence yesterday, discovered two vermiform appendices, which is said by the medical profession to be the only case of the kind on record. One was formed in the large intestine and the other in the smaller intestine.

In publishing the accounts of a vermiform appendix connecting with the small intestine, and pronouncing it the only case of the kind on record, it would be well for "the medical profession" to show why their second vermiform appendix was not the rather common developmental anomaly known as Meckel's diverticulum.

¹⁰ *Semaine Medicale*, 1896, p. 178.

THE AMERICAN MEDICAL ASSOCIATION ACCEPTS DENVER'S INVITATION.—Denver has been selected as the next place of meeting, and Dr. George M. Sternberg of Washington has been elected President of the Association. The other officers elected are as follows: Dr. J. M. Matthews, Kentucky, First Vice-President; Dr. W. H. Thompson, Indianapolis, Second Vice-President; Dr. F. H. Wiggins, New York, Third Vice-President; Dr. T. J. Happel, Tennessee, Fourth Vice-President; Dr. Henry P. Newman, Illinois, Treasurer; Dr. William B. Atkinson, Philadelphia, Secretary; Dr. W. A. Jayne, Colorado, Assistant Secretary; Dr. George W. Webster, Illinois, Librarian; Dr. J. W. Graham, Denver, chairman of the Committee on Arrangements.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, June 2, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 96, scarlet fever 54, typhoid fever 4, small-pox 1. For the week ending June 9th, the following cases were reported: diphtheria 76, scarlet fever 66, typhoid fever 1.

A DEATH FROM SMALL-POX IN CAMBRIDGE.—A man who had recently come to Cambridge from East Boston, and who was working on an estate in North Cambridge, died in that city last week of small-pox. He was quarantined in a cottage on the almshouse grounds.

THE BOSTON FLOATING HOSPITAL.—It is expected that the Floating Hospital, for which, as our readers will remember, a barge was purchased and thoroughly refitted last year, will make twice as many trips this year as last. A sick-ward with twelve beds has been fitted up on one of the decks.

SOLDIERS' FIELD FREE FROM MALARIA.—The investigation by the Massachusetts State Board of Health, instigated by the rumors that Soldiers' Field in Cambridge was malarial, has resulted in finding that the reports were without foundation. No illness occurred among some forty-five men who were employed in trenching the field and preparing it for athletic purposes.

DEATHS OF CENTENARIANS.—Mrs. Charity Green, who is believed to have been one hundred and five years old, an inmate of the home for Aged Colored Women, Myrtle Street, Boston, recently died from old age. She was probably the oldest woman in Boston, and was without kith or kindred, and dependent entirely upon friends. She was born a slave, was sold away from her husband, and had lived in Boston since 1854. She had been an inmate of the home for twenty-five years.

Joseph Gabaree died recently at West Georgia, Vt., at the age of one hundred and one years. He was probably the oldest man in the State. He was born

in St. Johns, P. Q., July 8, 1796, and removed to Georgia in 1823. He leaves ten children, the eldest of which is past seventy.

A DECISION OF IMPORTANCE TO PHYSICIANS.—

A case of interest to physicians generally was decided by Judge Dunbar, at Boston, last week. The circumstances of the case, as reported, were that previous to May 1, 1896, Dr. Oscar F. George had a lucrative practice in Lynn. On that date he sold it to Dr. Edward B. Herrick, who came from Amherst, Mass., signing an agreement not to practice in the city as long as Dr. Herrick remained there. He then went to Newburyport and later to Vermont, and about March 1, 1897, came to Swampscott, where he located and resumed practice, and, as he admitted upon the witness-stand, again began practice among his old patients in Lynn. Dr. Herrick brought a bill in equity in the Superior Court against Dr. George, to have him restrained from practising in Lynn. As a result Judge Dunbar enjoined the defendant from practising in Lynn in violation of his promise. The decision is important from the fact that, while the defendant admitted that morally he was bound to keep his agreement, legally he was not so bound. The judge, however, decided that he was both legally and morally bound to keep his agreement, and enjoined the defendant from further trespassing upon the ground to which he had signed away all claim.

DEATH OF DR. HENRY E. TURNER.—Dr. Henry E. Turner, one of the oldest practising physicians in Rhode Island, who had recently observed his sixtieth anniversary as a doctor, died in Newport June 4th, after a brief illness. He was born in Greenwich, R. I., eighty-one years ago, and early went to Newport, where he at once identified himself with local affairs. He was for many years city physician of Newport.

AN IMPORTANT DECISION IN FAVOR OF THE MAINE EYE AND EAR INFIRMARY.—The late Ira P. Farrington, of Portland, Me., left two-thirds of his residuary estate to the Maine Eye and Ear Infirmary, to be devoted to charitable purposes. Mr. Farrington's heirs-at-law brought a bill in equity to restrain the executors from paying the legacy to the infirmary, on the ground chiefly that by law the infirmary could not hold property in excess of \$100,000. They asked that the property so devised be distributed among the heirs. The defence contended that no one but the State could raise the point, and that the heirs had no standing in court in this matter. The court has just rendered a decision sustaining the contention of the defence. The amount involved is about \$200,000. The opinion was drawn by Chief Justice Peters.

NEW YORK.

COMMENCEMENT OF THE NEW YORK CITY TRAINING-SCHOOL FOR NURSES.—Mayor Strong presided at the twenty-second annual commencement of the New York City Training-School for Nurses at the

City (formerly Charity) Hospital on Blackwell's Island. There were thirty graduates who had pursued the regular two years' course at the City Hospital, and eleven others who had taken the six months' post-graduate course in the Maternity, Gouverneur, Harlem or Fordham Hospitals. The principal address to the class was made by Charities Commissioner John P. Faure.

OPENING OF THE FREE CITY BATHS.—The fifteen free city baths at various points along the East and Hudson Rivers were opened to the public on June 7th. At the last meeting of the Academy of Medicine a special committee was appointed to urge the Mayor to begin at once the erection of the public baths to be open throughout the year, for which the Legislature in 1895 appropriated the sum of \$200,000.

SMALL-POX STILL PRESENT.—The Board of Health has not as yet succeeded in its efforts to stamp out small-pox, and during the week ending June 5th four deaths were reported from the disease, against one in the preceding week. It is probable that a considerable number of cases will result from a young woman who on June 3d sat for two hours among the patients at the Vanderbilt Clinic, waiting her turn for treatment. When she finally came to be examined by the physician in charge it was found that she was suffering from small-pox. It is said that there were at least two hundred people in the rooms while she was waiting.

INFLUENZA AND GENERAL MORTALITY.—Last week there were no deaths from influenza, for the first time since the latter part of the winter, and the mortality from pneumonia and pulmonary tuberculosis, 73 and 83 respectively, was also the lowest of the season thus far. In the week ending May 29th there were reported 2 deaths from influenza, 79 from pneumonia, and 83 from consumption. The total number of deaths in the city was 703, representing an annual death-rate of 18.47 per thousand of the estimated population.

Miscellany.

THE HEALTH OF THE BRITISH TROOPS IN INDIA.

OUR British contemporaries have recently devoted a good deal of space to a discussion of the alarming prevalence of venereal diseases among the troops in India, and the marked increase which has taken place since the abolition of the Contagious Diseases Acts in 1888. These acts, which were an endeavor to regulate prostitution, were objected to as immoral from the fact that they recognized and licensed prostitutes, from the fact that they did injury to women by isolating them when diseased, and from their alleged failure as remedial measures. Nevertheless, the fact remains that since their repeal venereal diseases have enormously increased. Surgeon-Major J. B. Hamilton,¹ who has seen thirty-seven years' service in India, estimates that

¹ British Medical Journal, February 27, 1897.

on an average about 5,000 men are incapacitated by this disease.

At a recent meeting of the Royal College of Physicians, a committee which had been appointed to consider the advisability of approaching the government on the subject of the increase of venereal disease in India, reported that the extent of syphilis in the British army in India and its rapidly increasing prevalence are most serious. A visit to the Royal Victoria Hospital at Netley showed that on the day of the visit there were 752 patients in that institution, of whom 219 were cases of syphilis, many of them pitiable examples of virulent forms of this disease. The last troop-ship brought 312 invalids, of whom 76 were cases of syphilis. About 13,000 soldiers return to England from India every year, and about 60 per cent. of them have had venereal disease. The following extracts from the report show its general tenor:

The far-reaching effects of syphilis are so serious that it is of the first importance that the earliest indications of the disease should be medically treated without any loss of time; neglect of this measure tends to increase its virulence in all its stages.

As regards the unfortunate women who pursue their calling in a diseased condition, it is simply a matter of humanity to them that they should have the benefit of medical treatment, with rest and care in hospital, until they are cured.

In view of this lamentable prevalence of disease, your Committee makes the following recommendations and suggestions:

That as the civil, military, and medical officers in India are best acquainted with the local conditions now existing, and affecting this prevalence of venereal disease, so they are the best judges of the most efficient means of dealing with it. Your Committee, therefore, suggests that power be given to the Government of India to take such steps for the mitigation of this evil as these officers may advise.

That, for the protection of the healthy population, venereal diseases in both sexes—in the soldiers as well as the women—be subjected to the same restrictions as are other contagious diseases; such restrictions having for their object the detection and prevention of such diseases.

With regard to the unfortunate women, such measures necessarily include examination as well as treatment; and it may be desirable in India that the examination should be performed by persons of their own sex, who have been sufficiently trained and educated for the efficient discharge of this duty.

In making these recommendations your Committee considers that they should apply not only to the women, but also to the men with whom they consort; and is of opinion that it would be highly advantageous if medical officers in the army found some means, by elementary reading-room lectures or otherwise, of acquainting young and inexperienced soldiers with the grave and far-reaching consequences that are likely to result from immoral conduct, as well as from the concealment of the primary symptoms of the disease, the early treatment of which is of the utmost importance.

As a result of the attention called to the subject by the Royal College of Physicians and Surgeons, Lord George Hamilton, the Secretary of State for the Colonies has, in a dispatch to the Government of India, recognizing the extent of the evil, its appalling increase in late years, and the way in which the health of the civil population and of subsequent generations in England is imperilled thereby, urged that the canonment rules laid down in the Act of 1889 should not merely be applicable to "cholera, small-pox, diphtheria, or typhoid fever," but to all contagious and infectious diseases, including venereal disease. He mainly

adopts and follows the recommendations of the memorandum of the Army Sanitary Commission on the subject, and calls upon the Government of India to consider the whole question and to forward a copy of the draft rules proposed to be issued in order to give effect to the decision of Her Majesty's Government. The need which exists for the government proceeding warily if they are to avoid giving "occasion for the enemy to blaspheme" in a matter about which so much ignorance, prejudice, and false sentiment prevail, is emphasized in a recent editorial in the *Lancet*, which states that the government has safeguarded the moral aspect of the question.

The measures proposed, however, are so moderate and reasonable that the correspondent of the *London Times* at Simla voices the general opinion in India, that they will probably prove inadequate, and lays especial stress upon the clause in the despatch which directs that "no measure must be adopted capable of being represented as encouraging vice." It is rightly argued that no measures of repression of any kind could be devised which might not be misrepresented to be of a nature to encourage vice by the extreme opponents of all legislation or regulation. It is urged that the present concessions cannot prove that the final settlement of the question, and that the evils of the situation cannot be dealt with effectively until the Government of India is reinvested with full discretionary powers and allowed to adopt such measures, in concert with their medical and sanitary advisers, as commend themselves to practical men.

This question has very recently been the subject of a two days' debate in the House of Lords, in the course of which Lord Lister made his maiden speech.

A BACTERIOLOGICAL OBSERVATORY.

Science reports that the University of St. Petersburg has received a gift of 100,000 roubles from M. Ssimin for a bacteriological observatory.

This apparently unintended substitution of the word *observatory* for *laboratory* by our contemporary may be one of those chance mistakes in phraseology which accidentally emphasize important relations and resemblances between the meanings of the word which was meant and the one substituted.

Why could not a building devoted to the study of bacteriology be termed an observatory, with as much appropriateness as one devoted to astronomy? In both we have to do with the observation of natural objects by means of optical instruments of great power. One class of these is as far removed from the appreciation of our senses by the almost infinitesimal size of its components, as the other is by the almost infinite distances which intervene between the student and the subjects of his study.

The arts of photography and spectroscopy and the science of higher mathematics are called to aid the student of the one science, as chemistry, photography and pathology must aid in the study of the other. Yet accurate observation, controlled and checked by all the aids which can be brought to bear upon the subject, is as essentially the basis of bacteriological as it is of astronomical work. The student of one observes bacteria through a microscope, while the devotee of the other observes the stars through a

telescope. Why should the building where one line of study is pursued not be termed an observatory as well as that devoted to the other.

Obituary.

DR. BENJAMIN E. COTTING.

RESOLUTIONS OF THE VISITING STAFF OF THE BOSTON CITY HOSPITAL.

At a meeting of the Visiting Staff of the Boston City Hospital, held June 2, 1897, the following was presented:

In the death of Dr. Benjamin Eddy Cotting, The Boston City Hospital has lost the senior member of its Consulting Board, a place which he has held since 1868, a period of almost thirty years.

Always devoted to the interests of the profession he loved, he gave to this hospital his excellent judgment, which was cherished by his colleagues, not alone on account of his exceptional medical attainments, but also because it was broadened by wide travel and a deep interest in science, in advance of most of his contemporaries.

In him the hospital and the profession have lost one of the best examples of a broad, wise counsellor, typical of the best of his generation and rare in this.

Voted: That the above be entered upon the records, and that a copy be sent to the family of Dr. Cotting, and to the *Boston Medical and Surgical Journal* for publication.

Correspondence.

DRY FORMALDEHYDE GAS IN THE TREATMENT OF NASAL DIPHTHERIA.

BOSTON, June 4, 1897.

MR. EDITOR:—I desire to call attention to the use of an agent in the treatment of diphtheria, especially in locations not easily accessible to the ordinary topical applications for the disinfection or sterilization of local foci of the disease, or for prevention of its extension to other points. I allude to the employment of dry formaldehyde gas. I have not seen any account of its use in our vicinity, and have no other experience than that in one or two cases in which I have recently employed it. This is quite insufficient as a basis for more than a suggestion, and as such only I offer it.

The patient was a child of three and one-half years, very short and fat, who was observed to be ill on May 9th last, while in the country. She was brought to town the next day, before the disease had fully declared itself, and I saw her within an hour after her arrival. There was then extensive typical exudation over both tonsils, which were greatly swollen, completely occluding the upper part of the pharynx. A culture was immediately taken, although it was late at night, and by good fortune had so far progressed in the incubator by the next day that the diagnosis was made. Soon after this an injection of five cubic centimetres of antitoxin, from the supply furnished by the Boston Board of Health, was made in the left lumbar region. The younger brother of the patient, aged two years, was also given a protective inoculation of two and one-half cubic centimetres, as he had been exposed to the same chances of contagion as his sister (in which, so far as can be determined, the vehicle of infection was a pet rabbit of the neighborhood, with which many children had played a few days previously). He neither then nor subsequently presented any symptoms of diphtheria, or of any untoward effect from the antitoxin.

The patient had, on the whole, a fairly mild run of the disease, was treated in her own house, which was admirably adapted for isolation, and the spots disappeared from the throat in a few days; but the disease invaded the nose, and there persisted, being out of reach of any topical treatment. Repeated cultures always resulted in the presence of the Klebs-Löffler bacillus. After about sixteen days, an apparatus for the production of formaldehyde gas was obtained, and set up in a small room adjoining the sickroom, and the patient was exposed to daily inhalations of the gas in such strength that it caused abundant lachrymation, though it had no irritating effect upon the respiratory apparatus. From this time the patient improved rapidly, and after a few days bacilli entirely disappeared from the cultures and have not since been detected. I cannot but think that the inhalations were instrumental in this effect and that it was not simply a coincidence.

I report my result in the hope that the same means may be of service to others in the treatment of diphtheria. It seems to me quite the ideal treatment in infection of the nasal cavities, which are entirely inaccessible to management by most of the ordinary methods of treatment. A solution of formaldehyde had also been used as a gargle, and by evaporation over flame, but had no appreciable effect upon the disease. The change effected by the gas, however, was immediate and evident. I trust that others may be inclined to employ this agent, and report further experience.

Yours truly, ALBERT N. BLODGETT, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MAY 29, 1897.

Cities.	Estimated population.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported 3,086; under five years of age 913; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, diarrhical diseases and fever) 399, acute lung diseases 340, consumption 340, diphtheria and croup 170, diarrhical diseases 65, scarlet fever 47, typhoid fever 33,

measles 25, cerebro-spinal meningitis 23, whooping-cough 19, erysipelas 10.

From typhoid fever Philadelphia 16, Chicago 5, New York and Brooklyn 4 each, Boston and Cincinnati 3 each. From measles New York and Pittsburgh 7 each, Brooklyn 5, Chicago, Baltimore, Boston, Nashville, Fall River and New Bedford 1 each. From cerebro-spinal meningitis New York 8, Boston 6, Somerville 4, Baltimore, New Bedford, Malden, Newton and Quincy 1 each. From whooping-cough New York 5, Philadelphia 4, St. Louis 3, Brooklyn, Baltimore, Cincinnati, Washington, Charleston and Somerville 1 each. From erysipelas Philadelphia 4, Boston 2, New York, St. Louis, Cleveland and Providence 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,982,524, for the week ending May 22d, the death-rate was 17.2. Deaths reported 3,617; acute diseases of the respiratory organs (London) 220, whooping-cough 102, measles 97, diarrhea 43, diphtheria 42, scarlet fever 38, fever 34, small-pox (London) 1.

The death-rates ranged from 12.9 in Croydon to 23.3 in Liverpool; Birmingham 17.7, Bolton 16.3, Bradford 13.1, Cardiff 15.9, Gateshead 18.6, Huddersfield 17.5, Leeds 18.3, London 15.4, Manchester 22.0, Newcastle-on-Tyne 16.8, Nottingham 19.0, Portsmouth 20.3, Sheffield 20.9, West Ham 13.7, Wolverhampton 16.7.

METEOROLOGICAL RECORD

For the week ending May 29th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 28, 1897, TO JUNE 4, 1897.

Leave of absence for one month, to take effect on or about June 15, 1897, is granted MAJOR JOSEPH K. CONSON, surgeon, U. S. Army, Fort D. A. Russell, Wyo.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 7, 1897.

T. N. PENROSE, medical director, retired from June 6th.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE WEEK ENDING MAY 29, 1897.

MURRAY, R. D., surgeon. Granted leave of absence for four days from June 1, 1897.

PETTES, W. J., passed assistant surgeon. Granted leave of absence for twenty-three days from May 18, 1897.

STEWART, W. J. S., passed assistant surgeon. Granted leave of absence for three days from May 26, 1897.

BOARD CONVENED.

Board convened to meet in Washington, D. C., for physical examination of assistant surgeon EMIL PROCHAZKA, C. E. BANKS, surgeon, Chairman; G. T. VAUGHAN, E. K. SYRAGUE, passed assistant surgeons, Records.

RECENT DEATH.

DR. GEORGE THOMAS, professor of laryngology and physical diagnosis at the College of Physicians and Surgeons, Baltimore, died in that city recently. He was thirty-eight years old and a native of Maryland. He graduated from the Maryland Agricultural College and College of Physicians. Four years ago he was elected secretary of the faculty of the latter college. He was a member of the Maryland Clinical Society, and American Laryngological Society.

BOOKS AND PAMPHLETS RECEIVED.

Twenty-seventh Annual Report of the Superintendent of the St. Louis Insane Asylum. St. Louis, 1897.

Facts and Fancies in our Work. By Joseph Eastman, M.D., LL.D., Indianapolis, Ind. Reprint. 1897.

The Seventy-third Annual Report of the Officers of the Retreat for the Insane at Hartford, Conn. April, 1897.

The Biological Basis of Menstruation. By J. C. Webster, M.D. (Edin.), F.R.C.P.E., F.R.S.E. Reprint. 1897.

On So-called Idiopathic Dilatation of the Large Intestine. By C. F. Martin, B.A., M.D., Montreal. Reprint. 1897.

Primary Cancer of the Naso-pharynx Cured by Injections of Alcohol. By Edwin J. Kuh, M.D., Chicago, Ill. Reprint. 1897.

A Peculiar Form of Family "Tic Convulsif," with Nocturnal Exacerbations and Epileptic Attacks. By F. G. Finley, M.D., Montreal. Reprint. 1897.

On the Treatment of Fractured Shafts of Bone in Children; Simple, Complicated and Compound. By Thomas H. Manley, M.D., New York. Reprint. 1896.

Röntgen-Ray Skiagraphs. Surgical and Mechanical Relief of So-called Hopeless Paralytic Cripples. By DeForest Willard, M.D., Philadelphia. Reprints. 1896.

The Professional and Technical Schools, Especially those of Medicine, in their Relation to the College Course. By J. T. Eskridge, M.D., Denver, Col. Reprint. 1897.

The Annexation of Hawaii. An Address delivered before the National Geographic Society, at Washington, D. C., March 26, 1897. By Hon. John W. Foster, Ex-Secretary of State.

Report of a Case of Ectopic Gestation Associated with Tuberculosis of the Tubes, Placenta and Fetus. Fibro-Lipoma of the Kidney. By Alfred Scott Warthin, Ph.D., M.D., Ann Arbor, Mich. Reprints. 1896-97.

The Technique of Blood Study and Experiments in the Physiological Chemistry of Leucocytes. A Study in Cell Tissues and their Significance in Tuberculosis. By A. Mansfield Holmes, A.M., M.D., Denver, Col. Reprint. 1897.

A System of Medicine by Many Writers. Edited by Thomas Clifford Allbutt, M.A., M.D., LL.D., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physic in the University of Cambridge, Fellow of Gonville and Caius College. Vol. II. New York: The MacMillan Company. 1897.

Another Hitherto Undescribed Disease of the Ovaries. Anomalous Menstrual Bodies. Diagnosis and Some of the Clinical Aspects of Gyroma and Endothelioma of the Ovary. Carcinoma on the Floor of the Pelvis. By Mary A. Dixon Jones, M.D., Brooklyn, N. Y. Reprints. 1890-92-93.

A System of Practical Therapeutics. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia, Physician to the Jefferson Medical College Hospital. Vol. IV, with illustrations. Philadelphia and New York. 1897.

La condition nécessaire de la vie et de l'évolution considérée comme condition de la maladie et du dépérissement sénile de l'organisme. Introduction aux études cliniques. Par le Dr. C. Pawlinow, Professeur de clinique thérapeutique à la faculté de médecine de l'université de Moscou. Moscou, Alexandre Lang. 1897.

A Handbook of Medical Climatology. Embodying its Principles and Therapeutic Application, with Scientific Data of the Chief Health-Resorts of the World. By S. Edwin Solly, M.D., M.R.C.S., late President of the American Climatological Association. Illustrated in black and colors. Philadelphia: Lea Brothers & Co. 1897.

Lippincott's Medical Dictionary. A Complete Vocabulary of the Terms Used in Medicine and the Allied Sciences, with their Pronunciation, Etymology and Signification, including Much Collaborative and a Descriptive and Encyclopedic Character. Prepared on the basis of Thomas's Complete Medical Dictionary. By Ryland W. Greene, A.B.; with the Editorial Collaboration of John Ashurst, Jr., M.D., LL.D., Barton Professor of Surgery and Professor of Clinical Surgery in the University of Pennsylvania; George A. Piersol, M.D., Professor of Anatomy in the University of Pennsylvania; Joseph P. Remington, Ph.M., F.C.S., Professor of Theory and Practice of Pharmacy in the Philadelphia College of Pharmacy. Philadelphia: J. B. Lippincott Co. 1897.

Address.

AN EPOCH IN MEDICINE IN AN AGE OF DELUSION.¹

BY ZABDIEL BOYLSTON ADAMS, M.D., FRAMINGHAM, MASS.

(Concluded from No. 23, p. 561.)

It is humiliating! It is exasperating, to see how, in these times in which we live, fashion has become almost omnipotent in the realm of science and of ideas, and that it assumes to itself the same control over philosophic thought which it may properly claim to hold over the cut of our clothing, the decoration of our houses, or the manners of good society. In face of the impertinent interference of this tyrant in matters with which it has no concern, we seem to find but one comfort: We are living in an age of delusion which must pass away and give place to wiser counsels. I believe it to be a delusion which has crept into our universities in some measure, and also into the community at large, that the college is not a place exclusively designed to form the habit of scholarship, that young men enter it not alone nor principally to strive for high ideals, not to find the riches of literature, nor to encourage a love of knowledge for itself—in short, not more to train the intellect, than to train the muscles, to become proficient in various sports, or to excel in contests of strength or skill in gymnastics. I believe it to be a delusion to maintain that experimental biology (upon the lower animals) is cruel, and has never given to mankind any valuable knowledge; or that the phenomena of disease and health are controlled by psychical, or mental, influences entirely. I believe these things to be delusions, as it is a delusion to suppose that the unlimited coinage of a debased currency will bring about the prosperity of a nation.

The truth of the matter is this: The age of machinery and of cheap production has made it easy for all to supply the wants of food, clothing and shelter. We are paying the penalty of those who live in times of general prosperity and ease. The discovery of ether has robbed surgery of nearly all its horrors; while Christian charity and benevolence have increased the number and capacity of our free hospitals and provided for the poor, until no one needs to fear poverty or suffering. The creature forgets his creator. Industry, thrift and economy, have almost disappeared in the land. Irreligion, luxury and extravagance prevail in all classes of society. We are oppressed by the tyranny of "the common-schooled millions who have been taught to read but not to discriminate." There is a contempt for authority, almost no respect being paid to age, tradition or office. The faculty of independent judgment is weakened, "the acquiescent temper being cheaper than thinking," and popular success is made the criterion of merit. The virile power of the imagination is lost when we hear men sneer at chivalry and patriotism.

There may be something of the Anglo-Saxon love of fair play—the desire to side with the under dog—in all this. Nature's plan of evolution by the survival of the fittest is unjust and cruel to the weak. We must feel for whatever is low or depraved in humanity. Criminals should be looked upon and treated as the moral scrofulæ, the unfortunate, deformed children of men; and our sympathy should be given to them, and

not wasted on their uninteresting victims. The wise must not control the foolish any more than the rich the poor. In politics mediocrity comes to the top, bringing with it the dregs of communism. In art vulgarity is glorified, and is given the halo of veracity in contempt of all that is sincere and noble. Men and women live a hot-house life, and propagate and encourage the abnormal growths, the moral and intellectual "sports" of our nature.⁷

Indeed, we may say that society seems to be dancing *La Carmagnole*, while common-sense and good taste are "sneezing into the basket." Why should we have a cult of such dubious things as "the music of the future," the repulsive freaks of Japanese sculpture, dialectic poetry coarse and profane, or the drama and novels of "realism" which paint

"Coarse lusts of habitude.

Prurient yet passionless, cold studied lewdness
Depraving nature's frailty to an art!"

Fashion demands that we have new altars and new science. The worship of God as ordinarily understood being unfashionable, the very instinct of reverence apparently gone out of us, we have Theosophy or Rationalism; and in medicine we have "Christian Science" presented to us in a dish of the very froth of Bishop Berkeley's metaphysics, stirred into "clotted nonsense," and garnished with mottoes of Scripture and flowers of poetry. This has its churches and its gospel. It is a religion which with much justice claims to itself the soul of homeopathy; it is a science of medicine which, as some one has said, "deals with people's insides from the point of view of men who have no stomachs."⁸

Are there any who will say this picture is overdrawn, or that nearly the same state of things has existed before? Pardon me! This is not merely a case of the follies of an age confounding its wisdom. The vagaries of human thought have little to do with it. We may discard all that pertains to the supernatural as well as all the ferments of popular discontent, but the discoveries of modern science are simply incredible. The advance of surgery under asepsis excites the wonder of the world. Nothing now seems impossible. "The thing that could not have occurred." We feel as if invention had ceased to respect the mechanical paradox. The Ferris wheel and the ubiquitous bicycle are examples of this. Look at the seeming miracles of electricity! It has "put a girdle round about the earth in forty minutes"; it has, as it were, annihilated time and space. Listen at the telephone and phonograph! Examine the kinetoscope and skiagraph! See the bright light that burns without oxygen! See yonder loaded car drawn along our streets by no other apparent agency than a little wheel rolling upon a wire! The *fin-de-siècle* is to soar with the birds and to harness the lightning of the clouds! Are we not indeed encompassed by illusion more than ever before in the world's history?

Doubtless there have been physicians who have felt disheartened at the humiliation of our noble profession in this age of delusion. They may well have cried to God:

⁷ "The marriage vows are looked upon as grotesque, and it is considered ridiculous that little children should stretch out their arms to embrace a father and a mother."—The Great Physician, by François Coppée.

⁸ "It is instructive to reflect that the Paris which made Mesmer its idol was not far distant from the Paris of the reign of terror." A Book about Doctors.

¹ The annual discourse delivered at the Annual Meeting of the Massachusetts Medical Society, June 9, 1897.

"We look to thee; thy truth is still the light
Which guides the nations groping on their way,
Stumbling and falling in disastrous night,
Yet hoping ever for the perfect day."

There is yet another definition of our science, namely, that it is the theory of diseases and of their treatment. But among all the theories how to know the true one is the question. The only solid basis for a theory must be found in the facts of physiology and pathology. But beyond the pale of pathology there exists a *something* which cannot be accounted for, and must be reckoned with. No! what medicine has sorely needed has not been dialectics nor definitions, not theories nor systems, not even a greater mass of accumulated observations, classified, analyzed, made the basis of a true inductive science. Two things have been eternally wanting: first, the discovery of an efficient cause; second, the saving of human life and the cure of diseases through that discovery.

The evolution of the soul of a science is a slow process. Ages of time and many minds are necessary. The science of medicine has been a body without a soul.

When Newton saw the apple fall, and recognized and developed by an admirable deduction the great principle of gravitation, he gave to astronomy the soul that was wanting to a body of incongruous knowledge largely tainted with astrological superstition.

"Nature and nature's law, lay hid in night;
God said, 'Let Newton be,' and all was light."

When Lavoisier weighed the oxygen of the air he made the balance the ruling instrument of his science, and proved that all chemical action is only substitution. Thus was alchemy exploded and a soul given to chemistry, which then for the first time threw off the thralldom of magic, and took its appointed place as a noble and divine science.

In like manner when Louis Pasteur, perceiving that the essential element of fermentation was a living organism, disproved the doctrine of autogenesis, and by a bold deduction declared that all infectious diseases were caused by germs, he did for medicine what Newton did for astronomy and Lavoisier for chemistry. He emancipated it from empiricism, and gave to a body of unexplained and inexplicable phenomena which constituted the art of healing, the soul that was wanting to make a science of medicine. He had discovered an efficient cause.

The plan of my discourse leaves me no room to speak the eulogy of Louis Pasteur. The subject is a grand one. I confine myself to my topic, which is "An Epoch in Medicine in an Age of Delusion."

Let us briefly review the history.

Since the earliest dawn of civilization, and among savage and barbarous peoples, there has always existed the belief in some malign influence, some evil spirit or devil, which entered into the body, or dwelt in the body, and was the cause of sickness. All the theories and systems of medicine have recognized the existence of this "infection," sometimes supposed to be material, sometimes wholly or partly spiritual. The Egyptians, Greeks, or Romans, did nothing to advance our knowledge on this subject. The idea of minute animal or vegetable organisms as the cause of disease is not new;⁹ but, since the revival of learning in Europe, the nearest approach to the true explana-

tion was found in the doctrine of ferments. Until 1839, fermentation, however, was believed to be a *chemical* process.

The first halting step in this grand discovery was made when, in the early part of the last century, Lady Mary Wortley Montague brought the practice of inoculation from the East and Richard Mead inoculated the royal princesses of England with the small-pox; and, as far as this country is concerned, when Zabdiel Boylston and Cotton Mather introduced the practice in this State of Massachusetts. From two points of view this is now seen to be important. It was the first attempt, ignorantly and empirically made it is true, to create an immunity to disease by the artificial introduction of disease germs, or their products, into the human body. And secondly, when Jenner, in 1796, brought forward vaccination, the practice of inoculation with the small-pox virus was in vogue in England and readily accepted. Thus Jenner, veracious man that he was, was enabled to apply the *experimentum crucis* of small-pox inoculation to all those (or to many of those) upon whom he had tried his new process; and others followed his example. Doubtless "but for this fact, and this means of testing its efficacy, the practice of vaccination to prevent small-pox would not have found such ready and thorough acceptance by the world." This should never be forgotten. It is apt to be ignored by physicians, as well as others, who, trusting to the inadequate knowledge and experience of the present age in regard to small-pox, do not hesitate to question the value to the world of the practice of vaccination. The crucial test can no longer be applied, at least in civilized countries, but it is impossible to impeach the testimony of Edward Jenner in England, or of Benjamin Waterhouse in Massachusetts.

The next step, the discovery of Jenner, seems to have been only a happy inspiration which had a base no more solid than an observation of milk-maids.¹⁰ Here, again, we find a value not at first perceived. The facts disclosed by the practice of vaccination doubtless suggested the question of the true nature of susceptibility and immunity. The examination of this question led to another bold deduction by Pasteur, and brought about the discovery of the antitoxins.

In 1836, Dr. Oliver Wendell Holmes in a memoir on "The Contagiousness of Puerperal Fever," pointed out that infection could be carried on the hands or on the person of the physician from one patient to another.¹¹

In 1839, Schwan first clearly demonstrated the essential relation of the yeast plant to the process of fermentation, and Schönlein in the same year discovered the parasitic origin of favus.

Still these discoveries produced no valuable results to science, and it remained for Pasteur, in 1860, to conceive the idea that the acute infectious diseases were caused by the growth of microscopic parasites; a bold deduction which experimental biology has since proved to be correct. There now remained only the important question of the practical application of this discovery in saving human life and in curing human diseases.

The next step, and by no means the least important

⁹ Vide Medical Notes and Reflexions, by Sir Henry Holland, chap. xxxi, third London edition.

¹⁰ There is evidence to show that vaccination, or something like it, was practised before the time of Jenner, but the modern civilized world owes its introduction as a reliable method of preventing the spread of small-pox to Jenner alone.

¹¹ This was disputed by some of the highest authorities in this country.

one, was the introduction of antiseptic surgery in England by Lister.

Looking back as far as we may in the history of surgery we find that there was a *something* which nobody could explain, that caused surgical fever, and made the fatality of wounds and of surgical operations. That wise old surgeon, Ambroise Paré, declared that it was "miasms in the air which made wounds infect." Percival Pott, who had Wm. Cheselden for a pupil, is said to have employed a pretty fair antiseptic dressing; and others have used a variety of methods to prevent the access of air to wounds. But John Hunter declared that "we do not know, and probably never shall know, the cause of the fatality after wounds and operations." Simpson, of Edinburgh, in 1846, wrote, "It is only by employing the numerical or statistical method of examination that a perfect degree of accuracy of judgment can be possibly attained in such matters." So eminent a surgeon as the late Dr. Henry J. Bigelow told me, in 1866, that he had failed in every case of ovariectomy he had tried, and should never attempt those operations again; "but you, as others have done, will succeed," said he. The wonderful insight of that remarkable man was perhaps never better displayed than in this remark. It meant that there was "a something" which we did not know which made these operations fatal, and that "something" was to be found in the person of the operator.

Lister was not the first to suggest the notion of miasms in the air; nor of something in the hands or person of the surgeon, or in the instruments, or dressings which were used; Lister did not invent the antiseptics which he employed; least of all did he discover the fact that surgical fever, sepsis, or necrotic processes in the tissues, are caused by microbes. Yet, "as the originator of a system of wound treatment, his name will go down to posterity as having rendered incalculable service to humanity." His method has been essentially modified in nearly every particular, but "the great principle upon which it is founded will endure so long as a system of surgery exists."

It is to the investigations of Pasteur, Koch, and other bacteriologists, that we owe all that was new in Lister's method. These men proved by cultures, by vivisections and inoculations practised upon the lower animals, that sepsis, or surgical fever, the bugbear of John Hunter and of all surgeons up to that time, is caused by the growth of a microbe, a streptococcus, or staphylococcus, found upon the skin and mucous membranes of surgeon and patient, and also in air and water, which infects the wound during operation, or finds its way into the wound through the dressings; that these microbes exhale an odor resembling sour paste, that they do not require the presence of oxygen for their growth, that they are killed by a temperature above 150° of Fahrenheit, and also by contact with various substances now known as "antiseptics."

On the occasion of the "Fiftieth Anniversary of the First Public Demonstration of Surgical Anesthesia," Dr. McBurney said, "Bacteriology has penetrated with its brilliant light a darkness which our predecessors believed would last forever." And again he speaks of the wonderful discovery of aseptic treatment of wounds, "through whose agency countless thousands of human lives have been preserved."

And on the same occasion, Dr. Cheever said, "Hand-in-hand, equal benefactors, anesthesia and asepsis march calm and triumphant."

Yes! the saving of thousands upon thousands of lives, and "The future of surgery without limit," these are the gifts of asepsis to our science. We can say as Warren said of ether, "This is no humbug."

There now remained only the question of applying these discoveries to the cure of diseases.

Following out the suggestion of Jenner's discovery, many attempts have been made, chiefly upon cattle and sheep, to create an immunity to disease by inoculations, "but it is especially to the experimental researches of Pasteur that we are indebted for the development of practical methods." Pasteur made the discovery that susceptible animals, inoculated, or, as he said, *vaccinated*, with attenuated cultures of microbes, become immune to those microbes; that by a graduated series of inoculations a susceptible animal becomes fitted to receive without injury a pure culture of a virulent microbe, the effect being cumulative. The practical application of all this was made later in anthrax and hydrophobia, and it was shown that an animal can be made immune to the infection of these diseases, even when the poison has been carried into the body before beginning the protective inoculations; many experimenters working upon these discoveries. The next step was to find that this power resided in the blood-serum of animals which had been made artificially immune, and that this serum, filtered, sterilized, and thus rendered perfectly harmless, was not only protective, like vaccine, but in some cases also curative. Out of these facts came the invention of serum-therapy, with which you are all more or less familiar. These facts, of the highest importance to mankind, were demonstrated by vivisection and other experiments upon the brute creation, and they could be proved in no other way.

Thus it was that the discovery of the efficient cause was brought to the point of curing human diseases.

In spite of the convincing character of the evidence afforded by the facts of antiseptic surgery, there will be those who, persisting in the delusions of medical pharmacy, will question the value of Pasteur's discoveries, as was the case with inoculation in 1720, with vaccination in 1796, and with ether in 1846. The antitoxin treatment is only in its infancy, but of its ultimate victory over the minds of men there is no room to doubt. It is certainly unphilosophical, unreasonable, irrational, to contend that facts of this nature, which have been proved upon the lower animals, do not apply to man.

The invasion of the microbe into the body of pathology has raised many interesting questions. That of the true nature of racial, or family, or individual, susceptibility and immunity to certain diseases, remains, and probably ever will remain, unsolved.¹² We may expect to find that the antitoxins will not succeed in every case, for this is true of vaccination, and is suggested in the history of epidemics; but the cases of insuccess will be individual and exceptional. That the remedy will be found to apply to the great bulk of mankind may be safely asserted.

To repeat Dr. Warren's words again, "Gentlemen, this is no humbug."

Sternberg enumerates several hundred microbes which have been already obtained by bacteriologists and grown in cultures. Not all of these are found in man; but among them are the germs of nearly all the

¹² The personal equation can never be entirely eliminated from the problems of the physician.

most frequent and fatal maladies to which human beings are subject. Tuberculosis (consumption), cholera, the plague, typhus, typhoid and yellow fever, erysipelas, diphtheria, croupous pneumonia, meningitis, endocarditis, influenza, infantile diarrhea, besides the rare, but fatal diseases, anthrax, tetanus and hydrophobia, are among those found to be due to germs. The treatment by antitoxins has not been successfully applied in most of these, and the fact must be emphasized that much, we may almost say *everything*, is yet to be learned concerning the practical application of Pasteur's and Koch's discoveries.¹³

It is unbecoming in one who like myself is not a bacteriologist, nor even a microscopist, to enter upon the discussion of this intricate subject. The trend of biological opinion seems to be towards a vital, rather than a chemical or structural, explanation of immunity to disease. The vital properties of the proteids, of nuclein, globulin, etc., are beyond our chemistry, their molecular structure beyond the powers of the microscope, and it may be that too exclusive reliance has been placed upon the sense of sight in questions of germ pathology.¹⁴ We can set no bounds to the enlargement of our mental horizon by the revelations of physical science. Human ingenuity will doubtless find ways to enlarge the powers of our other senses. That which has been called "the sixth sense," and which has been nearly civilized out of existence in man, may, in ways not yet revealed, be made to assist in the examination of phenomena which are, like instinct itself, vital and functional rather than chemical or structural, and "other beneficent discoveries in the future may lead up to unimagined possibilities."¹⁵

There are perhaps enthusiasts who will exclaim that all this will revolutionize medical practice. I do not share in this feeling. It has been discovered that the specific action of quinine in malaria is due to the power of this drug to destroy the corpuscles of Laveran in the blood of the patient. It needs no seer to tell us that, as there are many surgical antiseptics, so there must be many remedies whose acknowledged therapeutic value will be found to lie in their power to destroy or expel pathogenic microbes, or to so immunize our bodies as to render these parasites inert and harmless in the fluids and tissues.

Dr. Roswell Park, of Buffalo, has indicated certain

¹³ One needs only to study the chapters on Pathogenic Bacteria in Sternberg's superb Text-Book of Bacteriology, to become aware of the fact that, indeed, we have no more than entered upon the investigation of this intricate subject, and must perhaps await the coming of another Pasteur to bring to fruition the wonderful discovery of the antitoxin treatment.

¹⁴ "The polymorphism of microbes finds analogy among the fungi, in which the 'pro-embryo' of Hofmeister often appears under many forms, 'always unlike the parent,' and the various orders of cryptogamia are seen to present remarkable differences in this respect."—Gray's Botanical Text Book, fourth edition, p. 341.

¹⁵ There are many interesting and suggestive analogies, or seeming analogies, between horticulture and medicine. The bacteriologist Toussaint—who was probably the first to show the practicability of conferring immunity upon animals by protective inoculations—discovered the fact that the bacillus of anthrax does not form spores in the body of an infected animal, but multiplies only by binary division of the mycelium. Thus when this microbe grows in a susceptible animal—as it were in a favorable soil where it flourishes most abundantly—it spreads by fission (increasing as fungi frequently do by multiplication of their vegetative cells, or as plants often do by offshoots or divisions of their roots and branches), and not by producing spores, which are the culmination of its vegetation, just as flowers (or embryos of the flowers) are the final product of the life of flowering plants. Now it is a fact familiar to the florist that many plants if grown in rich soil and thriving vigorously, run to wood, or leaf, or root, but do not flower. Again it is interesting to note that certain fungi which cause vegetable blight have a heteroecious development (for example, pear-leaf blight, the spores of which are the product of an apparently different fungus found upon the juniper), and that we have here an analogy to the supposed origin of vaccinia in "the grease" of the horse,—in which Jenner believed. These analogies may perhaps throw light on the origin of epidemic diseases, and explain the periods of interval or disappearance.

conditions of the system which tend to impair or destroy immunity or the power to resist microbic infection, and, therefore, may increase the liability to disease from this cause. These are toxemia and anemia, the presence of foreign bodies, paralysis of nerve influence, obstruction to circulation, to secretion or to excretion, hemorrhages, freezing, degeneration, etc.

It is also thought that resistance is diminished in parts where retrograde metamorphosis is going on, and that this explains the frequency of appendicitis, and of germ infection in the lymphoid tissues about the pharynx. Whatever tends to impair the natural vitality (such as neglect of hygiene and sanitation, crowding, privations and excesses, various poisons, exhaustion, the depressing passions, etc., and certain climatic, telluric or electric influences) encourages the growth of those microbes which are found within the human body, and which under favorable conditions may take on the character of virulence. The clinical symptoms of disease, then, are the signs of the struggle of nature to rid itself by the ordinary physiological processes of a parasitic pest, either by destroying it or neutralizing it. Thus we find ourselves again on the old Hippocratic ground. The first physician will be he "who knows how to wait for and to second the efforts of nature," as Herman Boerhaave declared nearly two centuries ago.

The prolonging of life is a boon only on the condition of relief from suffering; the field of symptomatic treatment is always open to the physician, and the grateful work is his of smoothing the pathway which all must tread to ineluctable death.

The department of the public health affords a natural field for the bacteriologist. But I do not propose to dwell upon this branch of the subject.

The value of serum inoculation as an aid to diagnosis has been shown by the employment of tuberculin in cattle. It seems to be now admitted on all hands that the rise of temperature which follows its use in diseased cows, is an established fact, and is a certain indication of the presence of tubercle in these animals. Other ways suggest themselves in which the antitoxin serum can be made useful in diagnosis and prognosis in man, and some have already been tried.

The work of Dr. Ferrán in Spain and of Haffkine in India, with anti-cholera vaccine, marks the first great step since Jenner's time in the direction of stamping out other epidemic diseases, as has been done with the small-pox.

Experiments in the Children's Hospital in this city by Dr. F. Gordon Morrill in the use of diphtheria antitoxin as a prophylactic, or an immunizing agent, have had encouraging success. But perhaps little can be accomplished in this way except in times of virulent epidemics. The inoculations seem to give a temporary increase of the power of resistance, but do not confer a vital immunity; and this is in accordance with the observation of other experimenters.

There may be diseases which are not due to microbes. Whether these are many or few, they cannot be included among those most dreaded and fatal. A development of virulent bacteria is almost invariably accompanied by a rise of temperature and other clinical signs of fever and inflammation; whenever there is contagion or infection, we must infer the existence of a germ.

But there is a class of disorders to which Sydenham

applied the name of "hysterical diseases." They furnish perhaps the major part of the daily practice of physicians. As the name implies they belong principally to women, but as man is born of woman he inherits her diseases.

It may be doubted if these disorders depend upon the growth of the parasites. They are peculiar to man, and have not been produced or studied in the lower animals. Hard-handed and primitive-living peoples are little liable to them. They are apparently weeds, or by-products, of the garden of civilization and refinement, anomalies, "sports" forced under steam culture, as it were; or they may be the *inheritance of the unnatural selection of the unfittest*, and such patients are prone to become victims of every form of medical delusion.

Generations may pass before the fruit will be fully ripe upon the tree which Pasteur has planted, but I believe the time will come when no instructed physician will talk of "healing the sick" by any other methods than those which shall grow out of these discoveries; and that he who continues to believe in so-called specifics, or who holds that the art of medical pharmacy is superior to all knowledge of the causes of disease, to the revelations of bacteriology, or the facts of germ-pathogeny—and ignores these things, must stand "marking time" in the ignoble army of charlatans and quacks.

Experimental biology and the bacteriological laboratory have become an integral part of our medical schools; for here is no theory and no delusion. The analogy between the phenomena of disease in the lower animals and those in man, will be found to be complete. The student is working not with *words*, but with *facts* of experiment and observation.

Let me recall to your minds the part which Massachusetts physicians have taken in these discoveries. Zabdiel Boylston, of Brookline, inoculated his only son and suffered social ostracism, in the cause of small-pox immunity. Benjamin Waterhouse, of Cambridge, introduced vaccination into this country, and proved its efficacy by small-pox inoculation in this vicinity. Oliver Wendell Holmes first pointed out the fact of personal infection. Here anesthesia was first practised, without which antiseptic surgery would be well-nigh impossible. Reference has already been made to various dialectic contributions by Fellows of this Society, pointing to these discoveries. These things are part of our history. To-day we find a hearty acclaim accorded by the profession here to the serum treatment, so that we may say with pride that, even in this age of delusion, this Society of Massachusetts physicians stands at the fore-front of scientific progress.

Gentlemen, we can but imagine the feelings of such men as Herman Boerhaave, Edward Jenner, Charles Louis, James Jackson, and others long dead, could they have seen their science brought through the slough of despond, and led to the gates of truth and light.

Without reservation we may now exclaim in the words of Bowditch, "The profession of medicine is man's noblest work, and the physician is God's vice-regent upon earth."

NOTE.—The course of the argument in this paper has called for a rehearsal—which must needs appear "stale, flat, and unprofitable"—of trite facts in the history of medicine, which otherwise should not be presented before the Massachusetts Medical Society without apology.

Original Articles.

RELATION OF NEURASTHENIC SYMPTOMS TO THE GENERAL NUTRITION.¹

BY ROBERT T. EDES, M.D.

THE opportunity offered by having under observation for periods often covering several months, a considerable number of patients with symptoms chiefly of the depressive type and for the most part not connected with known organic disease, has induced me to compare their progress with certain theories, or, perhaps I should rather say, feelings or assumptions, not always definitely stated but as it were "in the air"; to the general effect that these symptoms are largely or wholly dependent on insufficient or unsuitable nutrition, as displayed either by a certain amount of emaciation or anemia, or upon autogenetic toxic influences.

These impressions have in their support the highly important fact that no plan of treatment which affords a prospect of anything like enduring success can afford to leave them wholly out of sight.

So far as body weight, which of course depends on the harmonious working of more than one function, is concerned, by far the greater number of my cases seem to fully confirm the popular view. In the great majority a steady gain in body weight went hand-in-hand with improvement in nervous symptoms; sleep was better, general depression and nervous restlessness and local pain were less, and the brain increased its capacity for normal action without exhaustion. Little need be said about these. The results are what we expect and fortunately usually find.

Some special groups, however, may be selected which are partly confirmatory and partly incompatible with these ideas, which go to show that although the two processes of improved general nutrition and returning nervous strength do go so nearly hand in hand, they are not one and the same, and it is not always easy to say which leads. The first group consists of a certain number of cases, fortunately not large in proportion, which confirm the rule upon the other side, and go to show that a persistent refusal to take on flesh, notwithstanding rest and careful feeding with its adjuncts, is of decidedly unfavorable prognosis as regards speedy recovery, even when no other organic change can be discovered.

Miss D., age twenty-two, tall, with a delicate rosy complexion, lost weight from 148 to 125 pounds during eleven months, interrupted during one month by a slight gain. She had persistent backache and headache and frequent gastric disturbance. Since leaving the asylum she has had several severe turns of gastric disturbance originating at the time of menstruation but much outlasting it. Menstrual pain and backache have been somewhat better since the uterus was curetted, and her family recognize a decided improvement in the two years that have elapsed since her discharge.

Miss D., age thirty-eight, had tumors (supposed to be malignant, but after removal found tubercular), removed from one breast and axilla. A year later she entered the asylum, chiefly on account of general weakness and headache. She was of a singularly cheerful and hopeful disposition, but lost weight steadily though slowly from 113 to 104. There have been

¹ Read to the Association of American Physicians, Washington, D. C., May 6, 1897.

enlarged glands upon the other side, but no manifestations of tuberculosis elsewhere; and she remains an invalid.

Miss F., age twenty-eight, a chronic (probably congenital) neurasthenic, with choreic movements much aggravated by any mental disturbance, lost weight from 103 to 83 in a year. She is now supposed to be slowly improving.

Miss B., age twenty-five, lost seven pounds in nine months, and got back five of them in the next four. She improved greatly after a considerable time partly under the auspices of a faith-cure.

Miss H., age forty-five. Alternations of gain and loss for seven months, with a maximum variation of five pounds, and final loss of a pound and a half. Had severe neuralgic pains, chiefly sciatic. A short time after leaving the asylum she was sent to an insane hospital, but is now comparatively well.

Miss C., age thirty-three, had ups and downs of weight for nine months, at the end of which time she was half a pound lighter than when she began. She improved very slowly, and has continued to do so; but still she is not strong and does not sleep well.

Miss McC., age twenty-seven. Weight fluctuated for six months, ending with a total gain of half a pound. She is better, but not well.

Mrs. H., after a stay during which she was greatly improved, but unfortunately for my present purpose not weighed, was with us again for six months, during which her weight varied from 119½ to 122 pounds, but began and ended at 120. She developed distinct mental symptoms, and died some months later in an insane hospital.

Miss B., age thirty-eight, lost five pounds in four months. Her disposition was of the reticent, worrying and morose kind, which is not likely to be radically changed, and which continues to vary in its manifestations rather in accordance with the pressure of her responsibilities than with the state of her nutrition.

Miss G., age thirty, gained a pound or two in nine months, then lost six and gained four. There was no very decided improvement; but I have been unable to hear from her since.

Mrs. D., a large, flabby, pale woman, exhausted by large family, had ups and downs of weight for nine months, with a final loss of three pounds. She is in essentially the same condition.

Miss T., age thirty-seven, tall and thin, with a complexion of almost doughy whiteness and a low blood-color, has had a headache so persistent that the suspicion of an intracranial growth as well as of interstitial nephritis, has been often entertained but never justified. She has at times, but not constantly, gastric disturbance. She lost six pounds between July and August, which she made up again by November (during the gaining season); but since that time she has steadily lost again, and is now 9½ pounds lighter than when she entered. Her prospects of recovery at best seem very remote, although just now she seems to be gaining a little strength.

A catalogue of cases in which gain in weight took place with very decided but only temporary improvement would prove nothing but the too obvious fact that a fair degree of bodily and mental comfort may be maintained in the shelter of a hospital which cannot be continued after the patient has been again brought into contact with the labors and trials of everyday life.

In some cases the apparent improvement in nervous

strength lags so far behind that in weight, that the connection between them, even if real, is not very obvious. Mere timidity or lack of confidence resulting from too long a disuse of the powers actually present may restrain the patient from tests to which she responds well enough when the attempt is made with determination. If a faith-cure interfere at this stage, the bodily condition which makes it possible is very likely to be overlooked in wonder at the miracle. The following cases, however, were instances of a discrepancy more decided than mere delay between the bodily and mentally improved condition:

Miss E., age fifty-two, was the more than faithful and overzealous head nurse at a hospital. She experienced some sudden cerebral sensation, not attended with paralysis, from which she dated her illness. She gained ten pounds in four months, and improved greatly in bodily appearance, but remained in a condition of more hopeless despair without a trace of a delusion than is often seen outside the limits of melancholic insanity. Nearly two years later there had been no change for the better.

Mrs. S., age fifty-four, has gained twenty pounds in eight months, and has an excellent blood-color, but she sleeps hardly better than when she entered, and complains constantly of distressing thoracic sensations for which no anatomical basis can be found.

Miss R., age thirty-one, reticent and suspicious, had gained from 104 to 111, when her suspiciousness was noted as on the increase and becoming more definite. A few days later it was noted that her delusions were increasing, and she was discharged to the McLean Hospital.

Many other cases might be added, somewhat less striking, but going to show that the proportion of potential energy obtained by the nervous centres from a given amount of fat and blood may vary from almost nothing, as in the three instances just given, up to the normal as seen in the great majority.

A second group is composed of the cases where the gain in nervous strength takes place without any important gain in weight and is, when represented by what might be called acute cases, naturally enough not a large one in hospital practice. It is, however, amply supplemented by the very large number of such cases observed in everyday life, where normal and even excessive nervous and intellectual function is carried on with a degree of general nutrition below the average — cases which come under medical observation only incidentally or manifest such rapid recuperative powers that they do not become invalids at all. The hospital physician does not so frequently have the pleasure of seeing them recover, because they do not remain sick long enough to come under his care, and because also when they are submitted to a treatment directed toward this object they, too, can take on flesh, and thus seem to be specially good examples of the rule, while in reality this gain is only an accidental adjunct and in no way essential to recovery.

An easily recognizable subdivision of this group is found in the cases of normal weight, or perhaps even a little overweight, when a change in habits of life or of treatment may reduce it somewhat. An interesting instance of this occurred in Miss P., who gained six pounds in weight, but nothing in symptoms, during the four months in which she was treated for simple anemia and debility; but when her case was

recognized, somewhat tardily, as one of myxedema and treated by thyroid, she lost ten and a half pounds, with recovery. She was twenty-four years old, the youngest case I have ever seen of this affection.

A few cases of a more chronic character illustrate further the fact that the interdependence of the two sets of phenomena is not absolute, and, on the other hand, the great desirability of a somatic basis to ensure the success and permanency of psychic therapeutics.

than during the winter and spring. This has been before remarked of the growth of children.

I have placed underneath, as a matter of curiosity, a line representing the ratio of cases "discharged, recovered or relieved" to all discharges for five years. This is, of course, extremely vague, but might perhaps be interpreted to show a certain amount of correspondence between improvement in nervous symptoms and gain in weight, the latter showing its effect after a month or two. The fall and rise in the early

Miss C., age twenty-eight, brunette, lost two pounds in seven months (from 98 to 96), having in the interval gone for one month above 100 pounds. Her improvement in strength was steady and has continued.

Miss H., age twenty-six, with a complete paraplegia (undoubtedly of hysterical character) and obstinate resulting contracture, had not walked for eight years. She was not weighed for many months, but certainly did not gain greatly in flesh. She then lost steadily, from 91 to 87. After long-continued massage, passive motion and so on, she began to walk; and when discharged she could traverse the length of a long entry unassisted. Soon after her return to her home she was alarmed by a fire and relapsed, just how completely I do not know. She has made a second recovery under some form of faith-cure, which might easily have been more speedy than the first, as the contracture and the eight years' inertia no longer had to be overcome.

Miss M., age about thirty-five, increased from 132 to 160 in five months, and then gradually fell off to 150 without interruption in the progress of improvement.

An interesting incidental fact noticed when looking over the weight-records has been put in the form of curves, based upon three-year and two-year observations, that is, that the general gain in weight is considerably more in the later summer and early autumn

part of the year may depend upon the seasonal effect in preventing changes during the severe weather and a consequent removal to the country as the warmer months approach.

In speaking of the correspondence of nervous symptoms with anemia it is very necessary to take into account the ambiguity of the word, which is used on the one hand to mean a diminished blood-supply, and on the other a proportion of corpuscles or hemoglobin, or of both, diminished below a more or less arbitrary standard, or below the average.

When a local anemia is spoken of, it is usually the former, that is, a deficient supply, that is intended, for although it has long been known that the chemical composition of the blood varies within different portions of the arterial circulation, and recently the counts of J. K. Mitchell have shown that the corpuscles also cannot be distributed with absolute uniformity, it has not been usual to take cognizance of these facts in clinical language. The greater or less amount of blood in a given region can sometimes be estimated with some approach to accuracy, but it cannot be expressed in figures.

On the other hand, anemia, as a name of a disease or symptom without any anatomical limitation, is generally taken to refer to the latter condition, that is, deficiency of the blood in corpuscles or color which can be measured with a degree of accuracy not at all

commensurate with the apparent delicacy of the readings, but still sufficient to be of some value.

The total amount of blood in a given body it is quite impossible to measure without withdrawing a quantity inadmissible in modern therapeutics, and it can only be roughly estimated by comparisons of complexion, color of mucous membranes and blood-pressure, with measurements of hemoglobin or corpuscles. Facial complexion is specially fallacious as a measure of the amount of hemoglobin, and is much more dependent upon a proper degree of general and local vascular tension and cardiac vigor as well as upon individual differences in the capillary supply of the skin. The mucous membranes, especially the conjunctivæ, bring us somewhat nearer to a roughly correct estimate on the latter points.

So far as I have seen, an estimate of anemia based upon the general look of a patient is quite as likely to coincide with the severity of nervous symptoms as the measurements of the hemometer; but it is much less easy to put in figures. I am fully aware of the considerable limits of error in the latter instrument, even when used with great care, and I think I have ventured on no deductions drawn from small differences of individual readings.

The following table gives the blood measurements of a number of patients and employees, mostly females, divided into groups corresponding to each five degrees of Fleischl.

Female Patients.		Female Employees.		Male Patients.		Male Employees.	
1	1		1	100 or more	
2	1	1		2	95 to 100	
2	3	1		90 to 95	
3	10	2		1	1	85 to 90	
3	14	6		1	80 to 85	
4	20	8		1	1	75 to 80	
1	22	5		2	70 to 75	
5	15	7		65 to 70	
5	5	0		60 to 65	
6	7	1		55 to 60	
6	2	0		50 to 55	
7	3	1		45 to 50	
7	0	0		40 to 45	
8	4*	1†		Below 40	

* One each of 39, 36, 35, one below 15.

† One of 25.

It will be noticed that the highest numbers of cases among the patients come between 70 and 80, and among the employees no higher; so that it is fair to consider a color of 75, as measured by the Fleischl, a normal color among women who are not invalids but are not exceptionally robust.

It is impossible to draw any line which would distinctly separate the severe from the mild cases; but on going carefully over the list I am unable to detect any close correspondence of severity of symptoms with poverty in hemoglobin. On the contrary, it is easy to pick out from the higher classes several cases distinguished by especial severity and persistence of functional nervous disturbance, and among the very lowest the reverse.

Of five persons with a count below 40, two patients had hemorrhage from fibroids and suffered from some secondary symptoms, one from neuralgia, but were far from being of the nervous invalid type. Another was, to be sure, a hypochondriac, but of the comparatively cheerful type, if such a description be allowable.

One patient with pernicious anemia, having a blood-color less than 15, a count of less than a million, with extreme poikilocytosis, was indeed extremely nervous; but a laundress with color 25, a count of 700,000 and a complexion to correspond, hardly considered herself sick, and was entirely free from any nervous symptoms. A laundress with 55 and a table-girl with 45 are attending to their work.

A small woman with a pale and worn countenance, who was never weighed because she was supposed to be too weak to be put on the scales, and used to pour forth the longest and most voluble complaints of universal pains to which I ever listened, with complicated descriptions of paresthesiæ, nervous vomiting and sleeplessness, had a color of 75 and a count of 4,650,000. She was discharged not relieved. Another pale woman, with successive color-tests at intervals of a little over a month of 63, 61, 62 and 75, failed to gain weight, but was discharged relieved. She soon afterward became worse, and later insane, with final recovery.

Other similar cases might be found, but I will only mention three:

Mrs. M. has a somewhat sodden complexion, is weak, low-spirited and subject to gastric disturbance. Her blood-color, several times verified, is 86, which certainly seems to call for a more rapid recovery than she is making.

Mrs. S. has a complexion not pale but grayish, and without any flush. She has gained twenty pounds in weight, and her blood, which has been examined several times on account of the curious want of agreement with her appearance, always gives a color above 80. Her troublesome, but not absolutely constant, insomnia is not materially improved, nor the pain without discoverable basis, from which she constantly suffers.

Miss S. was sent in as a well-marked case of traumatic neurosis. She is distinctly of the hypochondriacal type. Her (legal) case has been settled. Her complexion would be described as pallid or perhaps even doughy; but her blood-color, although the estimates have varied somewhat, has usually been found over 80. She is, however, losing instead of gaining flesh, and there is no decided improvement in her symptoms.

(To be continued.)

MEETING OF THE AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION. — The next meeting of this Society will take place on Tuesday, Wednesday and Thursday, September 21, 22 and 23, 1897, at Harrisburg, Pa. The Harrisburg Academy of Medicine has offered the use of its building, and the Dauphin County Medical Society has appointed a special committee of arrangements to act for the Association. There is a promise of a fine display of electrical instruments and their practical operation. Secretary, Max Einhorn, M.D., No. 20 East Sixty-third Street, New York.

SPRAINS AND THEIR TREATMENT.¹

BY DOUGLAS GRAHAM, M.D., BOSTON.

My tailor is a very athletic fellow. He makes a specialty of spraining and bruising his joints; and I make a specialty of getting them well. He says he wishes that every doctor could have a sprain and have it treated by absolute rest and fixed dressings alone, and then that he could have another sprain and have it treated by means of massage and bandaging. This would be much more convincing than volumes of talking and writing, and would be almost the only way of converting the sceptical, who are dominated by the dogmatism of centuries, that immobilization is the best and only way of treating sprains.

The public in general have a very good idea of what a sprain is in speaking of it as a wrench or twist of a joint; but they have not a very clear idea of what it is *not*, in confounding it with a simple strain of muscle or fracture into a joint without displacement, or the first sign of weakness of a joint due to other causes.

What is a sprain? I was once present at a medico-legal examination where the attorney asked a very distinguished surgeon this question. He was so taken aback that I begged leave to answer it for him, which I did in the following words: "A sprain is a sudden, partial displacement of two joint-surfaces followed by immediate replacement; and if the patient has fallen from a height, there will be contusion of the joint surfaces as well. The attachments of the joint on one side are stretched beyond their natural limit; and on the other unduly compressed. If the patient has fallen squarely on a joint, there may be only contusion of its surfaces without strain of its attachments; and in this event the external symptoms may be slight or absent, while the discomfort is very great."²

My distinguished friend looked at me with a smile of relief and congratulation, evidently crediting me with the elucidation of a sprain on the spur of the moment. In this he was mistaken, for I had been studying it for some time, and had just constructed the above definition to suit myself, having previously searched the text-books in vain for anything like a satisfactory definition of the word "sprain." This was in 1888, and I have since had the pleasure of seeing this definition cribbed by good authority.

A few words with regard to influences predisposing to sprains may not be amiss. In some people I believe that there is a want of involuntary control in the nerve centres that preside over the muscles of the lower extremities. How else can we explain why some lackadaisical people frequently turn their ankles while walking on an even surface. In others, according to my own observations, high ankles are undoubtedly a predisposing influence. I have told many well people with high ankles that they frequently sprain them; and rarely have I been mistaken. The higher an ankle the more a lateral force at the edge of the foot will act upon it. The ankle admits of flexion and extension, and not of lateral motion, as many suppose. It might have been better if nature had allowed it some lateral motion, as this would probably have lessened the frequency of its being sprained. Indeed, some loose-jointed people have the faculty of turning

their ankles sideways to quite an extent without injury. But it may well be asked: How is it, then, that ankles are seldom sprained while skating? When skating the will, nerves and muscles are on guard over the ankle; at other times they are less likely to be so concentrated.

We need not spend much time with the symptoms and diagnosis of a sprain. When a patient complains of a joint, saying he does not know whether he has a sprain or not, we may be pretty sure that he has not sprained it; for a sprain makes itself known with tremendous rapidity, and always before a patient is quite ready for it. When it is accompanied with nausea and faintness as well as pain, it is apt to be pretty severe; and when, in the case of the ankle-joint, the patient cannot walk, we may suspect fracture.

The pain is attributed to stretching or tearing of the nerves, and its continuance to pressure of the effusion upon the ends of the nerves. Swelling, heat and discoloration are usually present. The least important of these is discoloration, for rupture of a very small vessel may cause a great deal of ecchymosis, giving the patient much alarm, in which the physician sometimes shares unnecessarily.

Immediately after a sprain there is often so much swelling, ecchymosis and general pain that a man with a brilliant imagination can diagnosticate anything he pleases — rupture of tendons, ligaments or fracture; the graver the diagnosis the better for the physician and the worse for the patient. A few massages properly given — by relieving the heat, the pain and the swelling — will often clear up the diagnosis wonderfully, and show whether there is a cracked bone or not. When the swelling does not disappear quickly under massage and bandaging, it is a pretty sure sign that we have something more than a sprain to deal with, probably a fracture without displacement of fragments, or possibly something worse, as I shall tell you farther on.

Opportunities for the examination of sprains after death are few, and these are probably of the most severe character. Literature on this subject is scarce and hard to find. Dr. Georges Berne, of Paris, has made some valuable researches, and to him I am indebted for much information about the nature of the injury. Sometimes the ligaments have been found broken, sometimes torn from their attachments. Moutard-Martin, at the autopsy of a man who had shortly before death sprained his knee, found rupture of the internal lateral ligament.³

The muscles are sometimes ruptured, and this usually occurs at their junction with the tendinous fibres. The tendons may be lacerated, luxated or expelled from their sheaths. Sedillot, in a sprain of the knee, found, after death, rupture of the muscles of the *patte d'oie* (aponeurotic expansion formed by the tendons of the sartorius, gracilis and semi-tendinosus at the upper and inner aspect of the tibia).

The synovial membrane has been found red and vascularized, sometimes thickened and covered by false membrane. There may be an effusion of fluid — serous, sero-fibrinous or sero-sanguinolent; at times, it has been found hemorrhagic. Unless the injurious force has been of a bruising nature, the larger vessels and nerves are seldom the seat of injury, as their yielding character protects them from rupture by traction or elongation.

² Treatise on Massage, by Douglas Graham, p. 261, 1890.

³ Société Anatomique, 1876.

It has long been a mystery to many of us why sprains of the fingers do so badly, as they have no weight to carry. This is well accounted for by the investigations of M. Ségond, who has found in these cases a constant lesion, namely, tearing of the two slips of insertion of the extensor tendon of the last phalanx, carrying away a small *sliver* (lamella) of bone, the terminal phalanx being flexed at a right angle. There was also dorsal ecchymosis.⁴

M. Lagrange has observed in his experiments on the cadaver, that after lateral forced flexion of the fingers, combined with slight rotation, there was tearing of the lateral ligaments not accompanied by any lesion of bone. When the finger was turned backwards in forced extension upon the dorsal aspect of the hand by a brisk push, a little cracking was heard. Dissection constantly revealed the avulsion by the anterior ligament of a slight linear transverse band of bone from either the proximal or distal side of the articulation. The areola of the spongy tissue were opened. In sprain of the metacarpo-phalangeal joint of the thumb, no lesion of bone was found. There was tearing or detachment of the external metacarpo-phalangeal ligament. Arthritis, or ankylosis is to be feared in these sprains of the fingers.

It is generally agreed that it is almost impossible, on account of swelling and thickening of the tissues, to make out an exact diagnosis in these cases. Time and treatment might help to clear it up, unless the treatments were of such a nature as to make the joint stiff. In due course of time, when it became evident that the tendon had become completely ruptured, suturing has been successfully performed. But this we have nothing to do with here.

According to old Nélaton, the best treatment for such cases consists in putting the finger in a palmar splint for eight or ten days, in order to favor repair; and after this massage and passive motion, thus hoping to avoid too prolonged immobility which might cause ankylosis. Better advice could not have been given.

A very little contemplation of such disastrous results as these would soon lead us to the conclusion that absolute rest and do nothing would probably be the best kind of treatment. And this reminds us of what Dr. Oliver Wendell Holmes used to say of the study of pathological anatomy, that it is a good deal like the study of the fireworks after the Fourth of July. It does not seem to us that complete separation of ligaments or tearing away of a piece of bone ought to be included under the head of the sprain. It rather conveys to us the idea that there may be sprain *plus* break of ligaments or detachment of a piece of bone, when the diagnosis can be made out. The old writers used to speak of "sprain fracture," which is an expression well put.

M. Castex sprained, bruised and dislocated the corresponding joints of dogs with equal severity. The muscles were also bruised. The injured limbs on one side of the animal were *masséed*, but on the other side they were not. In a few days the doggies that had been *masséed* could use their limbs freely while those which had not been *masséed* were stiff and lame and sore for many weeks. At the end of five or six months the dogs were killed, and the tissues of both sides were examined under the microscope. The muscular tissue of the side that had not been

masséed presented a diffuse sclerosis; the connective tissue intervening between the fibres and bundles of fibres was thickened; there were interstitial hemorrhages in the cellular tissue around the muscles; the internal and external coverings of the bundles of fibres were infiltrated with blood, and also the fascia outside of this. The transverse markings of the muscular fibres were effaced in many places, whilst the longitudinal striation or marking, which is not usually seen, was very distinct. The muscular tissue from the regions that had been *masséed* was found to be natural in every respect.⁵ M. Castex has forgotten to mention the appearance of the sarcolemma. In all probability this also was hardened, thickened and infiltrated with blood, as were the outer and larger coverings. The blood-vessels appeared perfectly normal from the *masséed* side, but from the other side that had not been manipulated they presented a hyperplasia of their external coat. The nerve filaments were found to be normal in the *masséed* side, whilst in the *non-masséed* side there were abundant evidences of perineuritis and interstitial neuritis, exerting destructive compression upon the nerve fibres. The perineurium was at least three times as thick in the *non-masséed* side, and the connective tissue around the perineurium was also thickened with numerous new-formed cells. The small vessels in the perineurium were also the seat of a peripheral hyperplasia. The changes in the nerves were more marked than those of the blood-vessels.

Clinical Department.

THE TREATMENT OF SPRAINS.

BY R. W. LOVETT, M.D., BOSTON.

INJURIES classified as sprains fall on closer inspection under one or more of four headings: these are contusions, ligamentous injuries, synovitis of the joint, and teno-synovitis of the muscles near the injured joint. So far as possible in my hospital work, I avoid the use of the word sprain, and aim rather at designating the particular injury as described above. In this way a step is made toward the more accurate study of these injuries.

The treatment which has been pursued is as follows: The mildest cases have been satisfactorily treated by daily massage and bandaging. I have never used immediate massage in severe sprains, perhaps from a feeling of timidity, but partly because I have seen cases of recent sprain made decidedly more acute from the application of massage in presumably competent hands. At the City Hospital we have facilities for massage; but in my term of service I have limited it wholly in the severer cases to the time when heat and excessive sensitiveness have disappeared, and when it seems to me desirable to stimulate the local circulation.

Our hospital out-patients recover more quickly and more completely than before we had massage facilities.

Taking the ankle-joint as a type in acute sprains, I have been able to obtain the best results by the immediate application of wet mill-board strips applied over several layers of sheet wadding, and bandaged tightly

⁴ Bulletin de la Société Anatomique, 1879.

⁵ Archives Générales de Médecine, 1891, 1892.

but evenly. This dressing is left undisturbed, except for additional roller bandages applied outside, for two or three days. At the end of this time, if the swelling has disappeared for the most part, if the sprain was a severe one, a circular plaster-of-Paris bandage is applied from the toes to below the knee. This bandage is split and removed every two or three days to note the progress of the joint. With the subsidence of the acute symptoms massage is begun, and the plaster at once reapplied for twenty-four hours. The plaster is discontinued gradually, to be replaced by a flannel bandage. Douches of hot and cold water are used in connection with massage.

The aim of the treatment is at first to quiet the general and local circulation by general and local rest, and thus to limit the effusion and joint irritation, and then at the earliest moment to revert to stimulating measures and restricted use of the recovering joint.

The immediate application of plaster-of-Paris is objectionable, because in twenty-four hours the swelling subsides somewhat, and leaves the plaster loose; or, if the swelling increases, discomfort or constriction may occur.

Half-way measures have little to commend them. Cotton bandages and hot water, however faithfully applied, are but poor makeshifts. Sticking-plaster is better, but lacks precision, although affording partial fixation; and in the ankle, applied as a figure-of-eight bandage, it often affords excellent support. But, in general, it may be said that a sprain is either slight enough to be treated by massage from the first, or severe enough to receive for a day or two, at least, the most complete and efficient fixation.

THE TREATMENT OF SPRAINS BY MASSAGE.

BY J. G. MUMFORD, M.D., BOSTON.

THE profession doubtless owes no slight debt to Dr. Graham for his enthusiastic devotion to massage and his aid in the revival of that ancient procedure based on logical and scientific principles.

Such treatment of sprains is probably the oldest in surgery. It has always been practised among the Orientals and was used by the ancients.

More recently Le Dran, early in the last century, wrote: "Impending inflammations about sprains may be checked and dispersed by the use of massage and kneading."

Sir Astley Cooper taught: "When there is much dispersed inflammatory exudate after fractures and dislocations use electricity and rubbings. It is the rubbings that do the work, and they should be deep and thorough."

Modern text-books scarcely mention massage of dislocations, and certainly do not give to it its proper importance.

For several years it has been my custom in both hospital and private practice to employ massage on sprains and dislocations as well as in certain fractures. Most surgeons are doing so to-day, I believe; and the results are interesting.

The old practice of immobilization of sprains is now generally conceded to be improper, for more than a few days. My routine practice, even in those cases in which there is considerable laceration, is to first use the hot and cold alternating douche for ten minutes to

allay pain, then to gently rub and knead about the injured joint for some fifteen minutes, and to apply a flannel bandage. Perfect rest for twenty-four hours is enjoined. On the second day more thorough kneading and stroking is done and a little passive motion is employed; and this is followed up daily.

As explained here the other night by Dr. H. P. Bowditch, it is in maintaining the proper nutrition of the parts by keeping up the flow of lymph that massage and passive motion act most effectively. Inflammatory exudate is thus carried off; but, more important still, proper nutrition of the parts is supplied by a passive motion substituted for the active motions of health.

In the case of a "sprained ankle" in which there is much extravasation of blood, teno-synovitis and escape of synovial fluid, the immobilizing treatment is most objectionable. By its use adhesions are apt to form, impairment of function with pain results, and where there is a tubercular taint proper conditions for a localized tuberculosis are established. The same is true of the wrist, knee, shoulder and other joints. By the use of properly applied massage these complications are obviated or overcome, and commonly a sound joint quickly results. I use the words "properly applied massage" advisedly, for this community abounds in illy instructed operators.

I believe the use of a skilfully applied flannel bandage is a very important and often neglected adjunct to this treatment. The surgeon should see to this himself. I have never found a masseur who was familiar with the proper principles of bandaging. The bandage should be broad, cut on the bias, and should cover with firm and evenly distributed elastic pressure all the parts as far as the adjacent joints on either side, with an extra pad over the injured joint itself.

After the first day I have the patient go about on crutches, in the case of a sprained ankle; and after the third day I encourage him to begin bearing a little weight on the foot. Two to three weeks often suffice to put such a sprained joint in a condition for careful use. We have all seen cases in which the immobilizing treatment resulted in an enfeebled limb after two or three months.

It is in the case of young and vigorous persons, football and tennis players and such others, that this treatment is most gratifying; and I have seen such men about their sports again after eight or ten days. In the case of sprained knees, with acute synovitis, these same statements are true.

With sprained wrists, in which there is a teno-synovitis, my experience with massage is not so happy. How often these cases develop tuberculosis, in comparison with similar injuries to the ankle I do not know. There are no statistics, I fancy; but I have seen a number of cases that went on to serious chronic disease under both methods of treatment.

I recognize the fact that statistics as to time of convalescence in all cases of sprains are of no great value, for convalescence must depend greatly on the character and extent of the injury; but I believe I am in accord with all who use massage in saying that clinical experience convinces one of the great usefulness of this method of treatment in properly selected cases.

A BILL has been introduced in the English House of Commons to legalize the Metric System.

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY.

ONE HUNDRED AND SIXTEENTH ANNUAL MEETING.

The meetings of the Sections in Medicine and Surgery were held in Mechanic Building on Tuesday afternoon, June 8th.

The Shattuck Lecture was given on Tuesday afternoon, by Dr. David W. Cheever, of Boston, on

THE NEW SURGERY.

The exhibits of apparatus and appliances shown this year were unusually good; and the x-ray photographs showed the marked progress in accuracy of delineation and definiteness of outline which has been made since the exhibit a year ago.

The practical demonstrations of fluoroscopy, under the charge of Dr. E. A. Colman, were very successful and excited a great deal of interest.

The exhibit of water-color sketches of pathological specimens, by Miss Byrnes, was remarkably fine, and the large colored anatomical drawings by Miss Saunders, made a notably good exhibit.

The One Hundred and Sixteenth Annual Meeting was held at Mechanic Building, Boston, Wednesday, June 9, 1897.

The following papers were read:

"The Diagnostic Value of the Examination of the Blood Serum," by DR. R. C. CABOT, of Boston.

"Fistula in Ano; Its Palliative and Operative Treatment," by DR. J. B. BLAKE, of Boston.

"Some of the Uses of the Röntgen Rays in Medicine," by DR. F. H. WILLIAMS, of Boston.

"Medical Inspection of Schools," by DR. S. H. DURGIN, of Boston.

THE ANNUAL DISCOURSE

was delivered at twelve o'clock by DR. Z. B. ADAMS, of Framingham, whose subject was "An Epoch of Medicine in an Age of Delusion."¹

THE ANNUAL DINNER.

PRESIDENT H. P. WALCOTT, in presenting the first speaker, Governor Wolcott, made the following address:

The medical year which draws to a close with this social meeting has been a notable one by reason of the great anniversaries which have been celebrated in it.

Our year began with the commemoration, after one hundred years, of the greatest discovery in the science of medicine, when Jenner on July 1, 1796, fully demonstrated the power of vaccination to withstand the poison of small-pox; and at the end of a century we hardly yet understand the mighty influence on medical practice of this and related methods for the control of disease.

Later in the year came the fiftieth anniversary of the discovery of surgical anesthesia, proved to be a fact by the use of sulphuric ether at the Massachusetts General Hospital on the 16th of October, 1846—the greatest discovery in the art of medicine; and, if second to any discovery in civilized times, it is inferior only to the art of printing. Again, the greatness of the invention has diminished sensibly our capacity to estimate its value, for hardly a man in this audience now

knows what the mental no less than the bodily tortures of surgery actually were in the days before anesthesia by ether.

If in the immediate history of this Society during the past year I find no events to be compared in startling importance with these two which have just been mentioned, let it not be understood that the progress of either the science or the art of medicine has come to a standstill.

In the opportunity for a wider acquaintance with the individuals who constitute this body throughout the State, which is one of the happiest privileges of your president, I have been struck with the lively interest everywhere displayed in the purely scientific aspects of our work; and it seems to me that there has never been a time in the history of medicine when there have been so many trained observers with such favorable conditions for good work as now.

The great discoveries will not always come when men most earnestly seek for them, but they very surely will not come unless men do seek for them; and so it is well for suffering humanity that our hospitals and medical schools are steadily improving in the means offered for scientific work, and nowhere is the prospect brighter than within the borders of our own State. If it were ever true, as some have imagined, that the more scientific study of the human body might lead to a degree of indifference as to the sufferings of the patient, it is surely not now true, when we have only to call the attention of the public to the evidences that surround us of the ever-growing care of the community for all of its component parts. The pauper receives a more effectual care at the State almshouse at Tewksbury to-day than the wealthiest man in Boston could have purchased a generation ago.

One beneficent result of the better science of medicine has been that we hear so much less nowadays of the schools of medicine or of doctrines in medicine. The wards of the modern hospital offer conditions for humane and profitable experiment which are but little, if at all, inferior to those of the biological laboratory; and there is, in consequence of all this, the usual disinclination on the part of a collection of scientific men to waste time on the idle declamations of those who never expect to give any scientific evidence of the truth of their assertions and would suffer a dogma to set the limits to scientific research.

True humanity has lost no portion of its divine quality in our efforts to extend the control of medicine over disease by laboratory methods of investigation; and it is not true that those who have carried on these investigations are inferior to their neighbors in their regard for suffering in man or brute.

Quite lately a president of the United States who on more than one occasion seized the opportunity to advocate the claims of scientific medicine, declared that the profession neglected a manifest duty in not insisting, as they easily might do, that legislative bodies should pay greater heed to their advice upon the questions essential to the health of the people.

Some of us have had opportunity enough to lament the ignorance of legislative bodies upon medical topics; but I should, for one, be sorry to see that ignorance removed by any other process than that of education, and the legitimate influence which each one of us can exert within his own limited circle of activity. I can imagine no greater engine of political influence than the associated members of this body if used in the

¹ See pages 557, 585 of the Journal.

ways taught us by demagogues; but, on the other hand, this Society never can be so used, for the individuals composing it have been so freely trusted with all that men hold sacred, that a breach of that trust would shake the very foundations upon which the honorable practice of medicine rests, and I know of hardly an instance where a breach of that trust has been rightly charged to a member of the Massachusetts Medical Society.

Combinations within the Society for any other purposes than those of improvement and social enjoyment seem to me a source of danger, greater than the good that might result therefrom. But the physician should always remember that he is, upon many questions, the most competent person in his community to give an opinion, and that he should never fail to exert in those matters the whole of the influence which belongs to an enlightened citizen of the State.

The Massachusetts Medical Society was incorporated under the laws of the Commonwealth in 1781. It has never been unmindful of the obligations imposed upon it by that charter, and is quite willing to submit its record to any investigation. The present chief magistrate was first our guest, if I am not mistaken, while a trustee of the Massachusetts General Hospital, and spoke to us in that capacity.

It is an especial gratification, then, to the Society to receive His Excellency, for we know that whatever judgment he may pass upon us, it will be founded upon an adequate knowledge of the task which medicine has undertaken and of the success of the performance. But there are other questions beside those that belong to medicine pressing upon the head of the State, and this Society rejoices in the opportunity to assure His Excellency of its absolute trust in his administration of them.

GOVERNOR WOLCOTT, who was greeted with hearty cheers, thanked the Society kindly for applauding him at the beginning of his speech instead of the end, for he feared that he must apologize for having so little to say on account of the pressure of official business to which he was required to attend during the closing days of the present legislative session. In reference to President Wolcott's remark respecting the various capacities in which he had appeared and addressed the Massachusetts Medical Society, he said that he reminded himself of a prescription given him by a member of the Society for a box of pills, of which he was to take two every hour until the ears rung. He had had to be taken annually by the Society, for four or five years, until their ears rung. He spoke of the importance of the members of the Society doing that part which they alone were qualified to perform in the furtherance of legislation for the promotion of the public health, and concluded as follows:

It is an interesting thing, to stand before this gathering. When a great body like this comes together the small, mean man is lost. The typical man, who approaches the ideal of the physician, is looked upon and examined. I will not attempt to say what, in form and feature and expression, is the type of the physician or lawyer or business man; but such meetings as this inspire all who attend with closer observation of that type. In it always two functions must be found in the same brain, in the same character—a broad, generous humanity, as well as the spirit of scientific investigation. To encourage this type your organization exists. And so the Commonwealth bids future pros-

perity and God-speed to the Massachusetts Medical Society.

The PRESIDENT then introduced the next speaker, Rev. Dr. George A. Gordon, of the Old South Church, Boston, as follows:

The practice and teaching of medicine began in the places consecrated to religious observances. The earliest hospitals were founded and maintained by the monastic orders, and this intricate relation of the care of the body to the care of the soul still exists, though the visible bonds have long since disappeared. In how simple and touching language a plain practitioner of our art in a Scotch hamlet has been drawn to the life by a Scotch clergyman you all know. This degree of appreciation could only come from one in the family, as it were. Dr. Gordon of the Old South cannot be out of place here.

DR. GORDON: In seeking to compare the medical profession with that to which I belong, I have learned that the medical profession have understood the use of anesthetics for no longer than the last fifty years. In my profession, for a thousand years we have been accustomed to put our patients to sleep before we operated upon them. It is possible that the thorough understanding which medical men have of the effects of anesthetics is the reason why we so seldom see them among our patients.

I am glad to hear again of the epoch-making discoveries in medicine to which your president has referred, and learn of the enthusiasm with which they are welcomed and put in practice by the medical profession.

When a new discovery is made in my profession there are always some among us who exclaim at first "It is blasphemous"; then, "It is against the Scriptures"; and last, "We have always believed it."

As your President has said, a Scotch minister has given the best and truest portrait of the virtues of the country doctor, the man who makes up the rank and file of the profession; and when Ian McLaren's book came out, it was easy to see how true it was to nature, for I observed that every physician with whom I was acquainted considered it an accurate portrait of himself. He considered it so for the reason that Dr. McClure was occasionally a little profane, because he was a hero among his patients, and because he pretended to care little for religion; yet on his death-bed what this physician wished to hear was the prayer he had heard at his mother's knee.

The training of the physician tends so strongly to develop efficient sympathy, and kindly, helpful relations with others, that a good physician cannot help being, in the best sense of the word, religious. I have noticed that while certain men are religious in spite of their profession, physicians are religious in virtue of their profession, and in spite of themselves!

I remember that, when I was a lad in Scotland, there were three men in the village to whom I was instructed to take off my hat: first, the parish minister; second, the parish school-master; and, third, the parish doctor. It is but natural, therefore, that I should find it easy to assume an attitude of reverence for the physician and I am proud to stand before this gathering of the Massachusetts Medical Society *with my hat off!*

The PRESIDENT then introduced Prof. J. B. Thayer of the Harvard Law School in the following terms:

Without the law, civilization would be impossible; and to this statement the medical profession willingly

assents, even though the law has at times undertaken to promote good surgery by the indirect and somewhat officious method of a suit for malpractice. Our guest, to-day, however, represents the law in its most benignant aspect, for no struggle of humanity has failed to receive his aid.

PROFESSOR THAYER alluded to the lack of proper respect on the part of Scotchmen for the legal profession, as shown by the fact that Dr. Gordon in his youth was taught to respect the other dignitaries of the village, while he was not instructed to take off his hat to the parish lawyer. While lawyers were, perhaps, according to the statement of the Scriptures, generally believed to subsist chiefly on widows' houses, he was glad to find that the President of the Massachusetts Medical Society recognized that the law had a benignant side.

Professor Thayer spoke of an attribute which he had noticed as common to physicians and lawyers, namely, the interest that each took in what was called a "pretty" case, which case, however "pretty" it might be from a scientific point of view, was seldom such from the standpoint of the patient or of his friends. He remembered hearing Emerson tell a story of the illness of an old friend of his, who was a prominent man in the country town where he was living, and relate how while on the way to his house to inquire for him, he met the doctor coming back smiling, rubbing his hands, and apparently in great glee. "And how is my old friend So and So?" Emerson said. "The prettiest case of apoplexy you ever saw," answered the doctor; "all the symptoms are absolutely typical, paralysis of the right arm and leg, livid skin, stertorous respiration, etc. It is seldom in a country practice that we see a case that comes up to the diagnosis in the books." All of which may have been very delightful for the doctor, but was rather sad news to the friends of the patient.

He then spoke of the limited extent of the associations of lawyers which he had been in the habit of addressing, such as the Boston Bar Association, etc., as compared with the extent and membership of the Massachusetts Medical Society, and said that not being a Methodist, it was very hard for him to address a regiment without embarrassment. He could hardly think of anything better for him to say than the words of the Texas murderer who had been sentenced to be hung, and was allowed before he was swung up to address the mob who had gathered to witness his execution. He warned his hearers against the sins of gambling and horse-racing. He said that he was innocent of the crime with which he was charged; and that he expected to go to heaven. Professor Thayer thought that in his position to-day he could hardly do better than warn his hearers against gambling and horse-racing.

He then went on to speak of a subject of great importance to physicians, a subject of which Judge Barker had treated in his address to the Society a year ago, namely, the necessity for improvement in the present system of medical expert testimony. He stated, as Judge Barker had done, that the chief difficulty in the way of having experts summoned only by the court, was the fundamental right of a litigant under our system of law, in trials by jury, to summon an expert who would present his side of the case. He could not be prevented from summoning any expert whom he pleased. A law, however, sanctioning

the summoning of experts by the court, who should adjudge the testimony of the experts summoned by the plaintiff and defendant, would in no way interfere with the rights of either, while it would do much to purify medical testimony and promote the ends of justice. He hoped that the members of the Society would use every proper means to secure the passage of legislation to this end, and believed their earnest efforts would be successful.

He then spoke of privileged communications to physicians, and the fact that in this State physicians on the stand were obliged to reveal all previous communications of their patients, while communications to lawyers the litigant had the privilege of revealing or not as he chose. He said that there was no real reason why a physician should be compelled to reveal the secrets of his patients on the witness-stand, unless the patient gave his consent. In various countries on the continent of Europe, the patient had the privilege of allowing his communications to his physician to be revealed or not, as he chose, and such a privilege in no way hindered the administrations of justice. The present law in Massachusetts ought to be amended so as to make this change.

After Professor Thayer's address, which, as well as Dr. Gordon's, received the interest and applause of the members, President Walcott introduced Dr. Henry S. Durand, of Rochester, N. Y., who read a poem.

A vote of thanks moved by the President to the Committee of Arrangements and its efficient chairman, Dr. A. K. Stone, for the remarkably successful management of the meeting and dinner, closed the exercises of the day.

The Harvard Graduates Glee Club, under the direction of Dr. Richard C. Cabot, sung several selections during the dinner, which were warmly applauded.

A pouring rain unfortunately prevented the participation of more than a very few of the members in the harbor excursion and visit to the battleship *Massachusetts*, which had been planned by the Committee of Arrangements.

MASSACHUSETTS MEDICAL SOCIETY.

COUNCILLORS' MEETING.

THE annual meeting was held at the Medical Library, Boston, on Tuesday, June 8, 1897.

The meeting was called to order at seven p. m. by the President, Dr. Henry P. Walcott. Ninety-eight Councillors indicated their presence by signing the roll.

The Secretary read the names of 152 Fellows admitted since the last annual meeting, and of 30 whose deaths had been recorded.

It was voted, on recommendation of the Committee on Membership and Finance, that \$3,000 of the surplus in the treasury be distributed among the district societies.

Voted, That the Treasurer be authorized to invest, or reinvest, the funds of the Society from time to time, as its needs and best interests shall seem to require, and in a manner approved by the Committee on Membership and Finance.

The Committee on Publications reported that Sir Wm. H. Hurgston, M.D., of Montreal, Canada, has

been appointed to deliver the Shattuck Lecture at the annual meeting of the Society in 1898.

DR. J. J. PUTNAM offered the following, which was adopted:

Resolved, That the Massachusetts Medical Society, recognizing the great value of the suggestions embodied in the report of the Commission appointed to investigate the public charitable and reformatory interests and institutions of the Commonwealth, hereby votes to petition the members of the next Legislature that these recommendations shall receive their careful and favorable attention.

DR. FITZ-HUGH presented the following, which was passed:

That the several District Societies be instructed at their annual meetings to elect one of their Councillors to be an alternate nominating Councillor.

The Committee on Nominations reported, and the following were chosen officers of the Society for the ensuing year: President, Dr. Henry P. Walcott, of Cambridge; Vice-President, Dr. Samuel W. Abbott, of Wakefield; Treasurer, Dr. Edward M. Buckingham, of Boston; Corresponding Secretary, Dr. Charles W. Swan, of Boston; Recording Secretary, Dr. Francis W. Goss, of Roxbury; Librarian, Dr. Edwin H. Brigham, of Boston. Dr. William T. Councilman, of Boston, was chosen Orator for the annual meeting of the Society in 1898.

Voted, That the next annual meeting of the Society be held in Boston on the second Wednesday in June, 1898.

The following Standing Committees were appointed: On Arrangements, Drs. M. V. Pierce, P. Thorndike, J. E. Goldthwait, M. Storer, W. H. Prescott, S. Crowell.

On Publications, Drs. O. F. Wadsworth, G. B. Shattuck, H. L. Burrell.

On Membership and Finances, Drs. F. W. Draper, J. Stedman, E. G. Cutler, L. R. Stone, F. W. Goss.

To Procure Scientific Papers, Drs. H. P. Bowditch, F. H. Zabriskie, H. L. Burrell, F. W. Chapin, C. W. Townsend.

On Ethics and Discipline, Drs. G. E. Francis, F. C. Shattuck, C. G. Carleton, E. Cowles, J. F. A. Adams.

On Medical Diplomas, Drs. H. E. Marion, E. N. Whittier, O. F. Rogers.

On State and National Legislation, Drs. H. P. Walcott, H. P. Bowditch, T. H. Gage, S. D. Presbrey, E. B. Harvey.

AMERICAN MEDICAL ASSOCIATION.

ABSTRACT OF THE PROCEEDINGS OF THE GENERAL SESSIONS OF THE FORTY-EIGHTH ANNUAL MEETING, PHILADELPHIA, PA., JUNE 1-4, 1897.

FIRST DAY.—TUESDAY.

The Association met in the Academy of Music, and was called to order at 10 A. M. by the President, DR. NICHOLAS SENN, of Chicago.

Prayer was offered by the REV. L. BRADLEY, D.D.

Addresses of Welcome were delivered by the HON. C. F. WARWICK, Mayor of Philadelphia, and HON. CHAS. EMORY SMITH.

DR. H. A. HARE, of Philadelphia, Chairman of the Committee of Arrangements, announced the receptions and entertainments.

The First Vice-President, DR. GEO. M. STERNBERG,

of Washington, D. C., took the chair, and PRESIDENT SENN delivered his Annual Address. He selected for his subject

THE AMERICAN MEDICAL ASSOCIATION: ITS PAST, PRESENT AND FUTURE.

He began by saying that the American Medical Association was born at the dawn of a great era in the history of medicine. Only a few years before its organization was effected anesthesia, which has robbed the operating-room of its greatest terrors, came into general use, and at once opened up new fields of usefulness for the surgeon. The new science of bacteriology, upon which is based our modern views regarding the etiology and prevention of disease, has been founded and firmly established since that time. The principles which govern the present treatment of wounds, conceived by the immortal Lister and developed to the existing state of perfection by a host of his enthusiastic followers, have revolutionized the practice of surgery during the last quarter of a century. Normal and pathologic microscopic anatomy are recent acquisitions to our knowledge of living tissues in health and disease. Aseptic midwifery is the direct descendant of aseptic surgery and has secured for the lying-in-woman the same protection against puerperal complications as the employment of aseptic precautions will prevent largely the occurrence of suppurative, sepsis and pyemia in the treatment of the injured and patients requiring operative treatment. Anesthesia and asepsis have created visceral surgery. Our knowledge of chemistry and physiology has been vastly increased during the last fifty years by thousands of earnest and devoted students in possession of improved instruments and apparatuses for accurate investigations. During the same time great strides have been made in the practice of medicine and the preparation and methods of administration of drugs. In the light of many of these recent advancements we have at least learned that disease is influenced for the better by aiding and assisting, rather than by combating and opposing nature's resources. Transillumination of the body by the wonderful Röntgen ray is the last and most important addition to our diagnostic resources in medicine and surgery. In those stirring events which have startled the medical world in such rapid succession during the last half of this century many members of our Association, dead and living, have taken a prominent and often leading part. In looking about for an appropriate subject for his address at this meeting he had deemed it expedient to utilize his time and this unusual opportunity in discussing as briefly as possible "The American Medical Association: its Past, Present and Future."

History has demonstrated the necessity of associated action in advancing the interests of the arts and sciences, commerce and the learned professions. The origin and the success of the American Medical Association have demonstrated the full meaning and force of this statement. Individual efforts accomplish but little in the correction of long-standing and widely disseminated evils. In 1835 the faculty of the Medical College of Georgia proposed the holding of a convention of delegates from all the medical colleges of the Union. This proposition met with little encouragement on the part of the remaining medical schools; and the first movement, which contemplated a convention of delegates, not only from all the medical colleges,

but also from the regularly organized medical societies throughout the New Republic, was made in the Medical Society of the State of New York, at the annual session in February, 1839. At this meeting, upon motion of Dr. John McCall, it was decided to hold a National Convention in the city of Philadelphia in 1840. The movement did not meet with sufficient encouragement to carry out the desired object. In the mean time the cause of medical education received a new and vigorous champion in the person of young Dr. N. S. Davis. He was born in the State of New York, January 9, 1817. Until sixteen years of age he assisted his father in managing a farm. After receiving the limited advantages of a rural-district school training he attended for six months Cazenovia Seminary. With this scanty preliminary education he entered upon his professional duties at Fairfield, in the old College of Physicians and Surgeons of the Western District of New York, and graduated with the Class of 1837, being then but a few days over twenty years of age. Endowed with a logical mind and great power of discrimination, he became impressed during his college life with the importance of a systematic graded course of instruction. His attendance upon lectures was arranged with such an object in view, and he is probably the first graduate of an American medical college who enjoyed the benefits of a graded course of instruction, which was arranged by himself and not by his Alma Mater. Ever since his graduation as a member of the American medical profession, and as a teacher, he has been an ardent advocate of systematic graded medical instruction; and the medical college which he later founded was the first one in this country to formulate and carry out his ideas. At the time he entered upon the practice of his profession in New York, the Medical Society of that State was fostered and guided by Dr. John Stearns. Almost from the beginning of his professional career Dr. Davis became a leader among his colleagues, and a strong advocate of much needed reforms in medical education.

Medical Education.—One of the principal subjects in view of the founders of the American Medical Association was to effect a much needed reform in medical education, looking toward a higher standard of preliminary preparation, lengthening of the lecture course and a systematic graded course of instruction. These objects have been nearly attained, and largely through the influence of the Association. Nearly all of our medical schools, large and small, now require four years' attendance, of eight months each, of a systematic graded course, and with few exceptions furnish adequate laboratory and clinical facilities. Our printed transactions, from the beginning of the Association until the present time, are loaded down with matter pertaining to medical education. This mission of the Association is about fulfilled. We have medical schools that are on a par with those of the older nations. There is no further excuse for our medical students to seek foreign universities to obtain a thorough medical education. Some of the very best practitioners of the United States are men who graduated in our own schools and who have never left their native soil. It requires no stretch of imagination to predict with certainty that our country will become the centre of medical education within twenty-five years and that our medical institutions will be sought by foreign nations, as they will in the course of that time furnish facilities for teaching far in advance of

those of any other country. Our medical schools are not tampered with by politics; and they are undergoing a rapid evolution by acquiring unlimited financial resources and by the ceaseless activity of the wide-awake, energetic and enthusiastic practitioners who by hard work and frequent intercourse with representative medical men at home and abroad become model practical teachers. The next function of the Association, as far as medical education is concerned, lies in another direction—post-graduate education.

Scientific Work of the Association.—The published "Transactions" and the volumes of the *Journal of the American Medical Association* are a mine of information for the general practitioner as well as the specialist, as they contain valuable contributions to medical literature, embracing all the departments of the healing art and the allied sciences. Many of the contributions have found a permanent place in our general literature and must be referred to by authors who write on the subjects of which they treat. It is a source of regret that many of the most important and interesting papers read during the early history of the Association have been buried in the volumes of the "Transactions." The value of these compendious volumes are, as a rule, underestimated by medical literary men, and are not consulted and quoted with the frequency they deserve.

Prize Essays.—Literary work in this country is appreciated only by the profession, and the only prospective reward is a consciousness of a duty performed and the recognition it may receive from the profession. Government recognition, such a strong stimulus to hard work in many of the countries abroad, is out of the question here. For the purpose of stimulating original research the American Medical Association during the first few years of its existence took the necessary steps to establish prizes for meritorious literary productions. The origin of awarding prizes for essays was from the following resolution offered by Dr. Alfred Stillé, while Chairman of the Standing Committee on Medical Literature at the Annual Meeting in Cincinnati, in May, 1850:

Resolved, That the sum of one hundred dollars, raised by voluntary contributions be offered in the name of the Association, to the best experimental essay on a subject connected either with physiology or medical chemistry, and that a committee of seven be appointed to carry out the objects of this resolution; said committee to receive the competing memoirs until the first day of March, 1851, the author's name to be concealed from the committee, and the name of the successful competitor alone to be announced after the publication of the decision.

It will be seen from what has been said that the prize essays of the American Medical Association take a high place in American medical literature, and it must appear plain to every one that the practice should be resuscitated. Authors and investigators should be encouraged in their work. The awarding of medals and prizes will encourage the younger members of our profession to apply their talent and energy in a proper direction. The recognition by the American profession of the merits of a literary production is a source of greater satisfaction to the author than the gratification afforded by the intrinsic value of the prize.

He would recommend as the greatest stimulus to original research the awarding of an Association gold medal for the best essay on any subject pertaining to the healing art. The gold medal to be offered by

and at the expense of the Association. He would suggest that one side of the medal should bear the bas-relief of the father of the Association, Dr. N. S. Davis, and the name of the American Medical Association; the other to be inscribed with the name of the successful competitor, the date of the award, with an Æsculapius staff in the centre. The ceremony of awarding the medal should be in public on the last day of the meeting of the Association, preceded by an appropriate speech by the presiding officer. The competitive essays should be placed in the hands of a special committee on prize essays three months before the date of the meeting, in the same manner as was customary in competing for prizes in the past.

It is time that the profession of this city, the home of the distinguished Benjamin Rush, should do something substantial to commemorate his memory. They can do nothing better than to establish at once, before this meeting adjourns, a Rush Memorial Prize, to be awarded for the best treatise on any subject relating to the science or practice of medicine. This city has an enviable reputation for its distinguished, enthusiastic and wealthy physicians, and he was confident they need only to be reminded of this late obligation to their most eminent colleague of the past, to step forward and subscribe the necessary fund of five or six thousand dollars. He was sure, if Benjamin Rush had a voice in this matter, he would prefer such a monument to one of marble or bronze. He hoped that in the near future every section will establish an annual prize. If this is done, we may expect a rich harvest of the most valuable contributions to indigenous medical literature.

American Medical Literature.—During the early history of our country students and physicians had to depend upon foreign authors for their text-books. With the Declaration of Independence came a sense of responsibility to our representative medical men to create a literature of our own. The first timid attempts consisted in translating or editing foreign books. The great evil of this then, and to a certain extent even now, too general a practice, did not escape the good sense and keen eye of one of the early members of this Association, whose name has become a household word throughout the civilized world—Oliver Wendell Holmes—who alludes to this subject in the following plain but significant language: "It cannot be denied that the great *forte* of American medical scholarship has hitherto consisted in 'editing' the works of British authors. The committee are not disposed to disguise the fact that this business has been carried on in a very cheap and labor-saving fashion. A tacit alliance between writers and publishers has infused the spirit of trade into the very heart of our native literature. The gilt letters of the bookbinder play no inconsiderable part in the creation of our literary celebrities. Sometimes the additions by the 'American editor' have been real and important, often nominal and insignificant." Dr. S. D. Gross, the Nestor of American surgery, and the foremost medical author this country has produced, raised his voice against such a parasitic literature at the meeting of the American Medical Association in 1850 by offering the following preamble and resolutions, which were unanimously adopted:

Whereas, The interests and dignity of the medical profession of the United States, as well as the true spirit of patriotism and a love of independence, demand that we

should use all proper and honorable means for the establishment of a National Medical Literature, and

Whereas, We have hitherto paid too blind and discriminate a deference and devotion to European authority;

Resolved, That this Association earnestly and respectfully recommend to the medical profession generally, and to the various medical schools in particular, the employment of native works as text-books for their pupils, instead of the productions of foreign writers.

Resolved, That the editing of English works by American physicians has a tendency to repress native literary and scientific authorship, and ought therefore to be discouraged by all who have at heart the object contemplated in this preamble.

Resolved, That this Association will always hail with satisfaction the reprints in their original and un mutilated form, of any meritorious works that may emanate from the British press.

Rush Monument.—He had mentioned Benjamin Rush in his address in various connections, but he felt constrained to refer to him once more regarding a movement initiated by Dr. A. L. Gihon, to erect to his memory a suitable monument in the city of Washington. The city of Washington is embellished and graced by many statues of the men whose lives are part of the nation's history. The services of presidents, heroes and patriots have been commemorated by the erection of statues of marble and bronze, the gift of an appreciative and grateful people. Law and science have been recognized in a similar manner by the erection of monuments, or costly oil-paintings, to the memory of the leaders in the legal profession, and the exponents of science and art, as a token of respect by the legal profession and the devotees to art. He hoped the Association would erect a suitable monument to Benjamin Rush.

Association Dinner.—The Committee of Arrangements are always severely taxed in procuring suitable entertainments for the members at each annual meeting. Much time and money have been spent for this purpose; and all of us can testify to the lavish hospitality extended year after year by the local physicians and public-spirited citizens. The evening receptions have been enjoyable, and conducive in bringing the delegates and members in closer contact. But he was sure they could not take the place of an Association dinner in making strangers friends, and in affording the best possible opportunities for an interchange of ideas and experiences, often of much more value than in listening to the reading of a scientific paper. Let us relieve our Committee of Arrangements of the greatest burden of their work and take the necessary steps to become independent, as far as our social enjoyments are concerned, by gathering around the festive board at our own expense. Section dinners have been a failure, and should be abolished. Let us have a dinner where the sturdy country physician can sit with his more nervous and excitable colleague from the city, where the surgeon can meet the physician, the physician with the specialists of all kinds,—that is, an easy, informal commingling of the different professional elements.

Evening Demonstrations.—It has occurred to him that the third evening of each session should be devoted strictly to scientific work of a special character. It seemed to him that nothing would prove more profitable and attractive than a lecture on bacteriology, histology (normal or morbid), illustrated by magic-lantern pictures from photomicrographs projected upon a screen. The lecturer should be chosen by the Nom-

inating Committee from year to year. We have an abundance of men well qualified for such a task within the ranks of our Association. A lecture of this nature, with numerous illustrations, would secure a large attendance, and would be one of the means of keeping our members informed of what pure science is doing for the healing art.

Permanent Home of the Association.—One of the present needs of the Association is a permanent home, with an editorial office and press-room for its official organ, a hall for the meetings (to be held at least every three years), which could also be utilized for the meetings of local societies, a library-room for American medical literature, and a memorial hall for paintings, busts of distinguished members of the Association, and a room for a collection of indigenous medical plants and surgical instruments, the invention of American physicians and surgeons. The site for such a home should be decided by vote of all members of the Association. The present financial status of the Association justifies the taking of the necessary steps to bring such a project into effect at an early date. He was sure the profession of the city that will be honored by becoming the site of such a wonderful institution will contribute liberally toward erecting and maintaining it. Such a modern Esculapian temple would soon become the Mecca for those in search of American medical literature, and a rich storehouse for everything pertaining to the medical history of this country.

Upon motion, the thanks of the Association were extended to Dr. Senn for his instructive address, and the recommendations were referred to the Executive Committee for action.

DR. A. L. GIBSON read the report of the Committee on Rush Monument, in which he said that the amount on hand was only \$4,016.19. The speaker considered Benjamin Rush one of the greatest American physicians that ever lived, one to whom American physicians owed the greatest gratitude, and who was deserving of the homage of every lover of his country because of the courage he had always exhibited and because of his martyrdom.

DR. CUTTER, of New York, moved that the Association appropriate each year \$1,000 until the requisite amount was raised.

DR. GRAHAM, of Denver, offered an amendment that the sum of \$100,000 be raised by members of the Association, and he pledged Colorado for \$2,000.

This amendment was carried, after which delegates from several States pledged \$2,000 each for their respective States.

DR. HENRY P. NEWMAN, of Chicago, read his report as Treasurer, in which he said that during the past year the Association had been very prosperous, in that its membership was steadily growing. There was now on hand a balance of nearly \$6,000.

AMENDMENTS TO THE CONSTITUTION

were then taken up and voted upon.

ARTICLE IV. — Officers. Amend to read, "each officer shall hold his appointment for one year, and until another is elected to succeed him."

On motion, this amendment was indefinitely postponed.

Executive Council. "That there be made an Executive Council of five, consisting of three officers of the Executive

Committee and two officers chosen by election. Of this council of five, one must belong to the Section on Practice of Medicine, and one to the Section on Surgery and Anatomy. To this Executive Council shall be delegated all the duties of the Executive Committee during the intervals between the meetings."

On motion, this amendment was adopted.

ARTICLE IX. — Conditions for further representation. "Any State or local medical society, or other organized institution whose rules, regulations and code of ethics agree in principle with those of this Association may be entitled to representation on the advice or agreement of the Judicial Council."

Indefinitely postponed.

To change the name of the Section on Dermatology and Syphilography to that of "Cutaneous Medicine and Surgery."

Adopted.

SECOND DAY. — WEDNESDAY.

The meeting was called to order by PRESIDENT SENN at 10 A. M.

The Address in Medicine was delivered by DR. AUSTIN FLINT, of New York City, who selected for his theme

STERCORIN AND CHOLESTEREMIA.

In Hoppe-Seyler's *Zeitschrift für Physiologische Chemie*, Strassburg, 1896, is a paper by Bondzynski and Humnicki entitled "The Destination of Cholesterol in the Animal Organism." The authors profess to have discovered a new constituent of the human feces, which they call *koprosterin*. This substance is identical with stercorin, fully described in 1862. The reading of this article led the speaker to repeat the original researches of 1862, carrying them out by the methods then employed, at the same time repeating the observations of Bondzynski and Humnicki with the methods and appliances used in their work. It was mainly an account of these new observations that he gave. The chemical manipulations were done by Dr. H. A. Haubold, assistant to the chair of physiology in the Bellevue Hospital Medical College, and J. A. Mandel, assistant in the department of chemistry in the College of the City of New York and to the chair of chemistry in the Bellevue Hospital Medical College. To these two skilful assistants he was indebted for most painstaking and accurate work, extending over a period of several months.

The original stercorin, of which specimens obtained in 1862 were in his possession, was extracted from the human feces by the following process: The dried and pulverized feces were extracted with ether. The ethereal extract was passed through animal charcoal and afterward evaporated. The residue was then extracted with boiling alcohol. The alcoholic extract was treated with potassium hydrate solution, at a temperature near the boiling point of water, in order to remove the fats by saponification, which were washed out with water until the filtrate was neutral and perfectly clear. The filter was dried, extracted with ether, and the ethereal extract evaporated to dryness and extracted with boiling alcohol. The stercorin was obtained from the alcoholic extract by repeated crystallization.

This process was exactly repeated in their recent observations, and, at the same time, stercorin was extracted by the process described by Bondzynski and

Humnicki. Normal human feces were obtained to the amount of about fifty pounds. After drying, the feces were divided. Two analyses each were made by Haubold and Mandel, each one extracting stercorin in one portion by the original method, and in the other by the new method. All the extracts obtained were identical in their composition, reactions and the form of crystals. It was fortunate that he had for comparison a fairly large specimen of stercorin extracted in 1862, and a microscopic slide bearing the date of June, 1862, in which the crystals were perfect. The product obtained by his process was a little more abundant and crystallized rather more readily than that obtained by the later method.

In the process employed by Bondzynski and Humnicki, the dried feces were extracted with ether, using Soxhlet's extraction apparatus. The fats were saponified with sodium alcoholate. No animal charcoal was used. The substance was purified by repeated crystallizations. These variations from the original method were unimportant, except in so far as they expedited the process of extraction. The form of the crystals and the reactions were identical with those which he obtained for stercorin in 1862. Analyses of the products obtained by them, full details of which were given in a paper sent to Hoppe-Seyler's *Zeitschrift*, gave, for stercorin, the formula, $C_{27}H_{48}O$, the formula found for cholesterol being $C_{27}H_{46}O$. The change of cholesterol into stercorin was effected by the addition to the former of two atoms of hydrogen. A close comparison of the results of their ultimate analyses with those obtained by Bondzynski and Humnicki showed conclusively that *koprosterin* and stercorin were identical, and that stercorin was not an impure cholesterol, as is held by some eminent investigators, such as Hoppe-Seyler, K. B. Hofmann, and others. Stercorin crystallizes in long, fine needles which radiate from a centre, forming tufts, and which cannot be confounded with the characteristic crystals of cholesterol. In a chloroform solution, stercorin gives, with an equal volume of concentrated sulphuric acid, first a yellow color and then a gradual change to orange, red and finally dark red. Treated in the same way, cholesterol promptly gives a blood-red reaction without these intermediate tints.

It is now generally admitted that the bile, in addition to its function connected with digestion, contains one or more excrementitious matters. Taking into consideration the various ingredients of the bile, there seems to be but one which can logically be compared to urea. Cholesterol is found in many of the tissues and organs of the body and exists in the blood. Liking it to urea, it becomes a question whether it is formed in the liver and discharged in the bile or is merely separated from the blood by the liver and excreted. As it is constantly found in notable quantity in the nervous tissue, in the proportion of eight to twelve parts in a thousand, it occurred to him to examine the blood of the internal jugular, and compare the proportion of cholesterol with that found in arterial blood. In one experiment, on a dog, the blood being taken without using an anesthetic, he found an increase in the jugular over the carotid of nearly 60 per cent. In an etherized animal the increase was only about 3.5 per cent. In another dog, not etherized, the increase was about 23 per cent. There was also an increase of from four to six per cent. in the blood of the femoral vein over arterial blood. In

three cases of hemiplegia, the blood from the arm of the sound side contained about the normal proportion of cholesterol, while blood from the affected side contained no cholesterol.

Passing from these observations to the pathological relations of cholesterol, after examining three specimens of normal blood, and finding the proportion of cholesterol from 0.445 to 0.751 of a part in a thousand, examinations were made of the blood of patients with simple jaundice and those with what is called icterus gravis, the cases terminating fatally with grave nervous symptoms. In a case of simple jaundice, terminating in recovery at the end of about four weeks, the blood contained 0.508 of a part in a thousand, well within the limits in normal blood. In a case of jaundice with cirrhosis, terminating fatally with serious nervous disturbance, the blood taken six days before death contained 1.850 parts in a thousand of cholesterol, an immense increase over the normal proportion. In this case, on post-mortem examination, the liver was found contracted, and the gall-bladder was shrunken, containing only about seven cubic centimetres of bile.

The question of cholesteremia has been much discussed since 1862, for the most part with scant approval or without acceptance. However, Picot, in 1872, reported a fatal case of "grave jaundice," in which he determined a great increase in the proportion of cholesterol in the blood, 1.804 parts in a thousand. Many attempts have been made, also, to produce toxic effects by injecting cholesterol into the blood, but most of them have been unsuccessful on account of mechanical obstruction of the blood-vessels. In 1873, however, Koloman Müller succeeded by injecting cholesterol rubber with glycerin and mixed with soap and water. In five experiments on dogs, injecting in each 0.045 gramme of cholesterol, he produced a complete representation of the phenomena of "grave jaundice."

In repeating the original researches of 1861, the observations, as regards analysis of feces, etc., were somewhat extended. With modern apparatus, the manipulations may be freed from many disagreeable features which heretofore, probably, have interfered with this line of investigation. In extracting stercorin, various volatile fatty acids and other substances were removed, the constitution and relations of which are unknown. They studied, in this connection, some of the products of bacterial action, obtaining, by the action of fecal bacteria on proteids, skatol and indol, both substances containing nitrogen. It is well known that phenol and cresol also exist in the feces. These nitrogenized matters are putrefactive products; nothing is known of their physiological or pathological relations; and up to this time stercorin is the only excrementitious matter yet found in the feces the origin and relations of which are at all understood. Our knowledge, indeed, of the physiological chemistry of the feces is only just begun; and we may look to future investigations for much that will be most important as well as interesting. The same might be said, in a measure, of the bile and of the true pathology of certain functional and structural diseases of the liver. How long shall we continue to speak of biliousness, congestion or torpor of the liver, the classic "liver complaint," *et id genus omne*, using terms which have no scientific meaning? Undoubtedly there are general disturbances, dependent upon some disorder in the functions of the liver, which occur without jaundice; and this fact has long been recognized.

In a case of cirrhosis with considerable constitutional disturbance but no jaundice, the blood was found to contain an excess of cholesterin 0.922 of a part in a thousand. In what is termed acholia, there may be grave nervous symptoms without jaundice; and the pathology of such cases is unknown. The biliary salts are not found in the blood, and the symptoms cannot be accounted for by disturbances in digestion. It is possible that light will be shed upon their pathology if it is admitted that there is a condition called cholesteremia. As yet this is but speculation; but if the theory of cholesteremia is accepted, a wide field of inquiry is opened in this direction, and ere long we may speak of "biliousness" and "liver complaint" with some definite ideas of their pathology.

With this paper he presented photographs of cholesterin, stercorin extracted by the original method, and stercorin extracted by the method of Bondzynski and Humnicki, all in 1897, with a photograph of crystals obtained in 1897 from a specimen of stercorin extracted in 1862.

PRESIDENT MCKINLEY was then introduced, and addressed the Association for one or two minutes. He said he could not refrain from pausing a moment that he might come into this brilliant presence to meet the learned gentlemen assembled, and to pay his respectful homage to the noble profession which they so worthily represented.

GOVERNOR HASTINGS followed with a few remarks in which he considered that the development of medicine had been greater than that of any other science. He thought it a mistake that monuments were not erected to the great masters of medical science in this country.

DR. H. C. WOOD, of Philadelphia, spoke forcibly on the Anti-vivisection Bill, and after giving a brief history of past legislation on the subject he emphasized the necessity of each member taking a personal interest in opposing the sinister and persistent efforts of the anti-vivisectionists. He offered a resolution against the passage of Senate Bill No. 1063, which was unanimously adopted.

THIRD DAY.—THURSDAY.

The Association was called to order by President Senn at 1 o'clock.

DR. FREDERICK HORNER presented a Report from the Committee on Organization of a Relief Association, and it was moved that the President appoint a committee of one from each State to establish such an association.

The Report of the Board of Trustees showed a satisfactory condition of the treasury, and also a steady increase in the circulation of the *Journal*.

DR. W. W. KEEN, of Philadelphia, was then introduced, and delivered the

ADDRESS IN SURGERY.

He said: As we celebrate on this occasion the semi-centennial of the organization of the American Medical Association in this city in 1847, it is very natural and proper that the Address in Surgery should be a review of the work done in the last fifty years, and by contrasting the state of surgery and of surgical teaching in 1847 with that which exists in 1897, to see what progress has been made. To account what had been achieved in these "fifty years of science," far better than a "cycle of Cathay," is not only a

pleasure, but it is an immense incentive, since, by the progress made in the last fifty years, we can in some measure anticipate the enormous and probably even still greater progress that will be made in the next half-century.

A most important factor in the improvement, not only in surgery but in all departments of medicine, has been the immense advance made in medical teaching. The educational plane of the profession has been steadily elevated. If the teachers of fifty years ago were to revisit the scenes of their early labors, they would scarcely recognize the medical colleges in which in their day and generation and with the meagre appliances then at their command, they did what we must still recognize as yeoman's work in education. Apparently at that time the entire instruction consisted in lectures, no text-book being even advised. In reply to the letter addressed to the deans of the Jefferson Medical College, the University of Pennsylvania, Harvard University, and the Medical Department of Columbia University, I am told that no lists of text-books whatever appear on the catalogues of fifty years ago.

Now, we may congratulate ourselves that the majority of the medical schools of the country have a graded course of four years, each covering not less than six and often eight months; not only lectures, but in many instances constant and searching recitations; almost a score of laboratories, in which each student actually does the work of observation and experiment; ward classes, in which every man is obliged to train his eyes, his ears, his fingers, and his judgment in the examination of patients in every department of medicine, to ferret out the history of the cases brought before him, ascertain symptoms, seek for physical signs, reach a diagnosis, determine the treatment, and often actually to prescribe and to assist at operations.

Allied to medical teaching and the most important adjunct to medical literature is the establishment of extensive medical libraries. In this, as an American, I am proud of my own country. No foreign nation can point with equal pride to any such medical libraries as the last thirty years have developed in this country. Foremost, not only among American libraries but in the world, is that of the Surgeon-General's Office of the United States Army in Washington. Not only has it gathered thousands of medical books and the 1,100 medical journals (the estimate of Dr. Fletcher) from all over the world, but the entire library is managed with a liberality which makes it the admiration and the envy of foreigners. Its treasures are freely at the service of the entire profession of the country; and the publication, under the editorship of Dr. John S. Billings, of its magnificent "Index Catalogue" has made the whole world debtors to America. We trust that a more liberal Congress may see that if even the small amounts thus far given to it have made it of such immense value, still larger and more generous appropriations would keep it ever in the van.

Dr. Keen then proceeded to dilate upon other noteworthy features upon which the development of modern surgery is dependent, declaring, among other things, that without anesthesia and antiseptics, modern surgery would be an impossibility. Animal experimentation, he said, had had also a very large share in the development of modern surgery. The whole question of the

introduction of animal ligatures was begun in America by Physick, who used buckskin; his follower, Dorsey, used kid, and cut both ends short; Hartshorne used parchment, and Bellenger and Eve used the tendon of the deer. The problem has been solved principally by experiment upon animals in order to determine accurately the behavior of such ligatures in the tissues. Only professional readers can appreciate what a boon to humanity this simple achievement has been. Modern cerebral surgery also owes its exactness and success almost wholly to cerebral localization and antiseptics, both of which were first studied by experiment upon animals, and later by the application of the knowledge so gained to man. Bacteriology would not now exist as a science, nor would accurate, modern surgery and a large part of modern medicine be possible had experiments upon animals been prohibited, as some zoophilist women, who love dogs better than men and women and even little children, desire.

Dr. Keen reviewed the surgical treatment of various cancerous diseases of the organs; and of appendicitis he said: The appendix, that meagre but most troublesome ancestral vestige, which with the bicycle has been the faithful friend of the surgeon through the past four years of commercial depression, has been recognized within the last few years as the real origin of the so frequent abscesses in the right iliac fossa. Beginning with Willard Parker's paper in 1867 and Fitz's memorable paper in 1886, the treatment of appendicitis, and even its much abused name, are distinctly of American origin and an immense credit to American surgery.

A hasty review, such as has been given of the improvements in surgery within the last fifty years, does much more than show us the adroitness, audacity and success of the modern surgeon.

That is the thing which strikes us most as surgeons; but we must regard all these improvements also from the side of the patient and the family, and see what it means. It means a prolongation of life by operations which, while not without pain and suffering during recovery, have been robbed of all their primary terrors by anesthesia, and of most of their subsequent pain and suffering by antiseptics; it means that patients who in 1847 were hopelessly consigned to the grave after weeks and months of suffering are now, in the vast majority of cases, rescued from death; it means that families formerly bereft of husband or wife, parent or child, and left to spend years of sorrow, of suffering, and, in many cases, of poverty because the breadwinners were taken away, have now restored to them their loved ones in health and strength and usefulness; it means that the hecatombs of a Caesar, of an Alexander, a Napoleon, are offset by the beneficent labors of a Morton, a Warren, a Lister, who are — and who for all time will be — blessed by many a poor patient who never heard of them, instead of being cursed as the destroyers of nations and of homes innumerable; it means that man's inhumanity to man shall be replaced by a scientific and Christian altruism which sheds blessings and benefits on the whole human race, seeing in the patient, whether saint or sinner, only a human being who is suffering from accident or disease, whom it is the province of the surgeon, in imitation of Him who went about doing good, to restore to health and happiness. Even where life cannot be prolonged, the agonies of death itself can be soothed by his hand and fruitful skill.

What the future has in store for us we can only dream. Two diametrically opposing tendencies are prominent in modern surgery: radical interference with disease, so that there is scarcely now a single organ or portion of the body not within our reach; yet, on the other hand, a remarkably conservative tendency in cultivating remedial rather than radical surgery. Joints so diseased as once to require amputation are now treated conservatively with the best results. Ovaries, a portion of which can be preserved, are kept in the abdomen; kidneys once doomed to extirpation are now partially removed, and bones so diseased that they then required amputation are now excised and the limb preserved. Experiments upon animals have recently given us wholly new views of infection and of the origin of many diseases, and also the little knowledge that we yet have as to either natural or acquired immunity and to a consequent orrhoterapy.

It is, he believes, on these lines that our more immediate future triumphs will be achieved. We have discovered the actual cause of tetanus, tuberculosis, erysipelas, suppuration, and a host of other diseases and conditions, of the causes of which we were wholly ignorant a few years ago. The causes of many other disorders, both medical and surgical, still remain hidden from our view. We know almost nothing of the origin of benign tumors, and are groping to discover the origin of cancer, sarcoma, and other malignant growths. When we have discovered the cause we are nearly half-way, or at least a long way, on the road to the discovery of the cure; and I think it not unlikely that in 1947 your then orator will be able to point to the time when a definite knowledge of the causes of these diseases was attained, and probably to a time when their cure was first instituted.

That will be a surgical paradise when we can lay aside the knife and by means of suitable toxins or antitoxins, drugs, or other methods of treatment, control inflammation, arrest suppuration, stay the ravages of tuberculosis or of syphilis, abort or disperse tumors, cure cancer, and, it may be, so prolong human life that all of one's then audience will die either of accident or of old age. Would that you and I could be alive in 1947 to join in the glorious surgical *Te Deum*.

JUBILEE EXERCISES.

The founder of the Association, Dr. N. S. Davis, of Chicago, then made his appearance on the stage, escorted by the Presidents of the various State Medical Societies and of the State Boards of Medical Examiners.

DR. JOHN B. ROBERTS, Chairman of the Committee on Anniversary Exercises, in a very appropriate speech presented Dr. Davis to President Senn.

DR. DAVIS was very warmly received on rising to speak. He read an address entitled

A BRIEF HISTORY OF THE ORIGIN OF THE AMERICAN MEDICAL ASSOCIATION, THE PRINCIPLES ON WHICH IT WAS ORGANIZED, THE OBJECTS IT WAS DESIGNED TO ACCOMPLISH, AND HOW FAR THEY HAVE BEEN ATTAINED DURING THE HALF CENTURY OF ITS EXISTENCE.

DR. JOHN B. ROBERTS said that diligent search had revealed that there were only four of the original members of the Association still living.

DR. GEO. BEN JOHNSTON, of Richmond, Va., followed with an address entitled

WHAT THE STATE MEDICAL SOCIETIES HAVE DONE FOR THE PEOPLE.

He said it was worthy of note that every State in the Union had to-day its medical society, and that, although their ages differed, all were filled with the same spirit and vigor of youth. In most States, there was formerly no requirement for a license to practise beyond the mere payment of a tax; but to-day all was changed, and now there was scarcely a State in which there was not a sufficient and well-executed law by which only qualified men were admitted to practise. The enactment of such laws as now exist was procured through the efforts of the State societies acting independently of each other; and there never was any well-directed attempt at co-operation, which accounted for the dissimilar character of the various statutes and the varying nature of the prescribed machinery for executing them.

DEATH OF DR. COCHRAN.

Resolutions were read and adopted regarding the death of Dr. Jerome Cochran, of Alabama.

FOURTH DAY. — FRIDAY.

The Association met at 10 A. M., and was called to order by PRESIDENT SENN.

DR. JOHN B. HAMILTON, of Chicago, delivered the address in State Medicine. He selected for his subject,

THE PREVENTION OF TUBERCULOSIS.

He stood, he said, by appointment in the place of the late Dr. Jerome Cochran, of Montgomery, Ala., whose pre-eminence in the science of preventive medicine easily singled him out from among his fellows as peculiarly fitted to deliver the Annual Address in State Medicine. His vast erudition, extended experience, and long public service made him *facile princeps* in all matters relating to sanitary work. Dr. Hamilton then paid a glowing tribute to the life and work of Dr. Cochran.

Coming to the subject of his address, he said that pulmonary tuberculosis alone took 345,963 lives in the five years, 1850, 1860, 1870, 1880 and 1890. These were the years in which the United States census was compiled.

In the 28 largest cities of the German empire, the number of deaths from consumption per 100,000 of the aggregate population during the year 1890 was 299, ranging from 453 in Nuremberg, 367 in Dortmund, 357 in Frankfort-on-the-Main, 388 in Crefeld and 353 in Elberfeld to 236 in Königsberg, 249 in Strasburg, 239 in Halle and 247 in Chemnitz.

The average annual number of deaths from consumption per 100,000 of inhabitants for the ten years, 1881 to 1890, was, for Paris, 463; Nuremberg, 457; Dortmund, 417; Barmen, 381; Aachen, 377; Frankfort-on-the-Main, 373; Crefeld, 373; Bremen, 392, and London, 206. The death-rates from consumption in most of the large cities diminished during the ten years 1881 to 1890. The difference in the mortality from consumption in the large cities of the United States depend largely upon differences in the proportion of different races in the several cities, and, also, to some extent, upon the age, distribution and density of population, on the depth of the level of subsoil

water, and on the dryness and uniformity of temperature of the climate. As a rule, the death rate from this cause in large cities is greater than it is in the small towns and rural districts.

General Measures of Relief.—The humanitarian turn to science for relief from this "great white plague," so destructive, so elusive, and so calamitous; and it is now the province of State Medicine alone to point out the methods by which we may put this plague "upon a basis of gradual extinction."

The prevention of tuberculosis cannot be accomplished in a day, but its ravages may be made less by such prompt measures on the part of our boards of health as may easily be taken, provided the laity are taken into confidence. The public must be fully educated to an understanding of the causes and method of propagation.

Heredity.—The heredity of the disease has been established by Baraud and Rénou, who reported to the Société de Biologie of Paris, in June, 1895, that they had investigated the question of the direct transmissibility of the bacillus through the placenta to the human fetus. In five cases they took a quantity of blood from the umbilical vein, and injected it under the skin of the abdomen of guinea-pigs, immediately after the birth of the child. In three of the cases the guinea-pigs did not become tuberculous, while in two they did. In the first case the mother was in the first stage of phthisis, the sputa containing bacilli. There were no lesions of the placenta present, apparently. The guinea-pig which was injected developed a chancreous ulcer at the point of inoculation, and died with tuberculosis of the liver and spleen at the end of two months. The bacilli were found in the spleen, pulp and in the caseous masses of the chancreous ulcer. An autopsy performed on the still-born infant gave negative results. Three guinea-pigs were injected with the juice of the pulp of the lung, liver and peritoneal serum, and two of them died. In the second case, the mother had pulmonary cavities, but no examination of the sputa was made. The child died of broncho-pneumonia on the fortieth day. The placenta presented a normal appearance. At the moment of birth, blood from the umbilical vein was injected into two guinea-pigs; one pig died of generalized tuberculosis, the other lived.

Solly, of Colorado, holds that a connection between phthisis in an individual and phthisis in the family may be exercised in one of three ways, namely, by inheritance of bacilli, by inheritance of susceptibility, or by contagion.

Lehman has reported a case of congenital tuberculosis, where a mother died three days after the birth of the child, of tuberculous meningitis. The child lived but twenty-four hours. In its spleen, lungs and liver were found nodules resembling tubercles and containing tubercle bacilli in large numbers.

Hahn has collected and reviewed some cases of tuberculosis where they were undoubtedly congenital. The semen may also become infected and thus transmit the disease to the fetus. Gärtner caused tuberculosis in young mice by injecting the mother with tubercle, either into the peritoneal cavity or into the blood stream.

Baumgarten detected the tubercle bacillus in the ovum of a female rabbit which he had artificially fecundated with tuberculous semen.

Infection by Milk.—There is no longer any ques-

tion of the possibility of infecting the lower animals by the injection of tuberculous milk, but direct evidence of transmission of tuberculosis by milk in man by ingestion is not yet positive, except in cases of udder tuberculosis.

In cows with tubercular disease of the udder, the Royal Commission found that the milk was in every case infective, and the experiments made by inoculation in every case gave positive results. As regards feeding, 27 animals were fed with varying quantities of milk from cows with tubercular udders. Of these 27 animals, 19 developed tuberculosis. The brunt of the disease in these cases fell on the abdominal organs, showing the alimentary origin, but in some cases also there was a more generalized infection. The glands about the mouth and angle of the jaw were also found sometimes tubercular.

Dr. Martin, in speaking of these experiments, says: "The milk of cows with tuberculosis of the udder possesses a virulence which can only be described as extraordinary. In those cows where the tubercle bacilli were found in the milk, the feeding experiments were uniformly positive as well as the inoculation experiments. It is noticeable, too, that a small dose of the milk diluted four times gave tuberculosis to all the animals fed, and that a dose of even .05 to .1 cubic centimetre diluted with non-infective milk was sufficient to produce tuberculosis."²

It is well known that many cattle are affected with tuberculosis in this country, that the milk goes into the general supply, and that tubercle bacilli may be found in the milk in cases of udder tuberculosis, and that rabbits inoculated with infected milk or fed upon infected milk, become tuberculous. Dilution with non-infected milk attenuates the bacilli, and the dishonest practice of watering is therefore not without its compensation.

Dr. Gehrman, of the Chicago Health Department, after testing the milk from tuberculous cows, writes: "In only one specimen of milk was it possible to demonstrate the presence of the tubercle bacillus microscopically, but in thirty-eight injections of the milk in animals we had the transmission of tuberculosis demonstrated six times."

Infection by Tuberculous Meat.—Tubercle bacilli have been found in the flesh of horses, cattle and swine. Birds and fowls also become infected, and when dogs and cats become infected it is said that they become so by reason of eating flesh of tuberculous animals, but this lacks corroboration by extended experiment.

The review of the recent reports on this branch of the subject corroborates the former view that careful cooking of meat and boiling of milk before eating or drinking these articles will prevent them from doing positive harm, but few would relish food if it were known to be tuberculous, even if cooked by a Lucullus. An act passed this year, by the Maine Legislature, provides for the killing of all diseased animals, the injection of kerosene oil into their carotid arteries, and the burial of the carcasses within twenty-four hours or their reduction to fertilizing material within forty-eight hours.

To sum up, it appears that the greatest danger is from the dried sputum, and that other causes, while they exist, are of much less importance. The local infections that are found in the bones and internal

viscera are produced by invasion through the circulation, while the infection of lymphatic glands doubtless takes place by direct absorption through the lymph channels. Every surgeon has noticed without doubt that tuberculous glands become successively affected; it is the exception to find a whole chain of glands simultaneously affected. When the tubercular lesion is found in the skin the point of invasion is an abrasion; or a centre beginning in the hair follicle.

The means of prevention of the spread of tuberculosis are then sufficiently apparent after we have taken our observations on the methods of infection. The factors in successful prophylaxis are: (1) The guarding against infectious food or drink being issued to the people anywhere. (2) The prompt destruction of cattle proved to be tuberculous. (3) Proper notification to the sanitary officer of the occurrence of cases of pulmonary consumption.

Marriage of the Tuberculous should be Opposed.—The law prevents marriage within certain degrees of consanguinity; no account is taken of the physical state of the contracting parties, although in many States certain physical causes are sufficient reason for divorce. If chronic and incurable disease be sufficient ground for separation, how much more reason is there for the prohibition of the marriage rite. The insane and incurably diseased should not be allowed to propagate their species, unless we confine our sympathy to the individual instead of the whole people. The heredity of the disease has at last been fairly proved by scientific investigation. Public opinion should now do the rest.

Richardson's "City of Hygeia," that beautiful fabric of a vision, as one of our countrymen has said, "was blown away by the winds, but they blew it all over the earth." So the wide dissemination of correct knowledge concerning the cause and propagation of tuberculosis cannot but tend to still further restrict its ravages, and thus add to the sum of human happiness and the prolongation of human life.

The following officers were elected for the ensuing year:

President, Dr. George M. Sternberg, Washington, D. C. First Vice-President, Dr. Joseph M. Mathews, Louisville, Ky. Second Vice-President, Dr. J. L. Thompson, Indianapolis, Ind. Third Vice-President, Dr. J. W. Wiggin, New York, N. Y. Fourth Vice-President, Dr. T. J. Happel, Trenton, Tenn. Treasurer, Dr. Henry P. Newman, Chicago, Ill. Assistant Secretary, Dr. W. A. Jayne, Denver, Col. Librarian, Dr. Geo. W. Webster, Chicago, Ill. Chairman, Committee of Arrangements, Dr. J. W. Graham, Denver, Col.

Board of Trustees: Dr. J. T. Priestley, Des Moines, Ia.; Dr. Joseph Eastman, Indianapolis, Ind.; Dr. Truman W. Miller, Chicago, Ill.

Judicial Council: Dr. D. W. Cronse, Waterloo, Ia.; Dr. T. D. Crothers, Hartford, Conn.; Dr. Wm. T. Bishop, Harrisburg, Pa.; Dr. R. C. Moore, Omaha, Neb.; Dr. G. B. Gillespie, Covington, Tenn.; Dr. C. H. Hughes, St. Louis, Mo.; Dr. Ida J. Hieberger, District of Columbia.

The Annual Addresses were allotted as follows: On General Medicine, Dr. J. H. Musser, Philadelphia, Pa.; On General Surgery, Dr. J. B. Murphy, Chicago, Ill.; On State Medicine, Dr. S. C. Bussey, Washington, D. C.

Adjourned to meet in Denver, Col., in 1898.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JUNE 17, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS.

**EIGHTY-THIRD ANNUAL REPORT OF THE
 MASSACHUSETTS GENERAL HOSPITAL.**

THE Annual Report of the Massachusetts General Hospital for the year 1896 has recently appeared.

The most striking event of the year in the history of the hospital was the celebration at the General Hospital, of "The Semi-Centennial of Anesthesia," October 16, 1896, that day being the fiftieth anniversary of the day on which occurred at the Massachusetts General Hospital, the first public demonstration of surgical anesthesia, an event which settled for all time the future of anesthesia. The addresses and poem, it will be remembered, were published in full in our issue of October, 1896. The poem, addresses and other details of the proceedings have been embodied in a handsome memorial volume lately issued.

On October 9th, the gift to the corporation, by Dr. Wm. S. Bigelow, of a bust of his late father, Dr. Henry J. Bigelow, was announced and the following vote was adopted:

Voted, That the thanks of the Corporation be given, through the Trustees, to Dr. Wm. S. Bigelow for his most acceptable gift of his father's bust; that it be placed in the Bigelow Amphitheatre, and that Dr. Wm. S. Bigelow be invited to act as a committee in selecting its position.

The tables of Medical and Surgical Statistics, which were omitted in 1895, are here continued, this report containing the tables for 1895 and 1896. They show a large amount of medical and surgical work with excellent result.

It appears from the surgical tables that in 1895 there were 131 cases of appendicitis operated on, of whom 16 died—a mortality of 12 per cent. Of those, 106 were acute cases, with 16 deaths; 25 were chronic and recurrent, with no deaths.

In 1896, 157 cases of appendicitis were operated on, 15 of whom died—a mortality of only 9.5 per cent.; 94 of these were acute, with 15 deaths; 63 were chronic or recurrent, with no deaths.

In 1895, there were 37 patients operated on for

"radical cure" of hernia, without a single death (this is, of course, exclusive of strangulated and incarcerated hernia). In 1896, there were 98 cases operated on for "radical cure" of hernia, with one death. In the three years during which these tables have been published there have been 184 operations for radical cure of hernia, with only one death, a mortality of a little more than one-half of one per cent. During the same period there have been done 119 hysterectomies for cancer and fibroid tumors of the uterus, with 12 deaths, or 10 per cent.

The cases most largely represented in the medical wards have been typhoid fever, pneumonia, Bright's disease and heart disease, the above diseases constituting 34 per cent. of the medical admissions in 1895, and 29 per cent. in 1896.

In the Out-Patient Department during 1896, 29,867 new patients were treated.

The Training-School for Nurses, which a year ago was transferred by its managers and made a part of the Massachusetts General Hospital, has, as in the past, done admirable work. During the year 72 nurses were in regular training and 32 were graduated. Many of the physicians and surgeons of the hospital staff lectured to the nurses, and regular instruction in massage, cooking and dietetics was given. The value attached to the instruction given in this training-school is indicated by the fact that there were 836 applicants.

During 1896 Hon. Roger Wolcott and Mr. Thornton K. Lothrop resigned their membership in the Board of Trustees, and Messrs. George Wigglesworth and Samuel D. Warren were elected to fill their places.

Dr. J. W. Pratt, who for ten years has filled the position of Resident Physician of the General Hospital, and who, during that time, has won the cordial goodwill of all his associates, resigned June 1, 1897. In accepting his resignation, the trustees express their appreciation of the admirable qualities which Dr. Pratt has displayed during his long term of service, and their wishes for his future success.

The Report of the Superintendent of the McLean Hospital shows that 258 cases were treated during 1896, and 125 new cases were admitted, of whom 80 were regarded as recent cases, and 45 as chronic or incurable.

The average duration of illness from the beginning of attack in all cases recovered was 7.28 months, and the average duration of their residence in the hospital was 4.32 months. The percentage of recoveries on all admissions, for the year 1896, was 18.9.

The 49 voluntary cases admitted during the year, with 32 such cases remaining from previous years, furnished 10 recoveries. The voluntary patients have yielded 20.41 per cent. of recoveries on the admissions of that class for 1896, thus furnishing a little more than their due proportion of all the recoveries. Of this class, 6 other cases were discharged much improved, 12 improved, 15 not improved, 1 dead and 2 not insane.

Excellent work has been done in the laboratory

which has been recently established, under the direction of Dr. August Hoch; and some progress has been made in developing the methods of clinical work in connection with that of the laboratory with its facilities for investigation.

Exercise for its direct remedial effects in the form of physical training, by general and medical gymnastics, including outdoor exercises, has been under supervision of the instructors in physical training. The indoor facilities for gymnastics were limited, being confined to the occasional use of the new entertainment hall for the men, so that much attention was given to outdoor exercise for them. In one of the gardens there was arranged what was practically an open-air gymnasium. The gymnasiums for men and women will soon be occupied for recreation, exercise, and work in the shops.

The report of the McLean Hospital concludes as follows:

The experiences of the first year in the new hospital were attended by many causes for care, and even anxiety in its practical affairs. But the natural difficulties due to the new conditions have been overcome so far as to give assurance of harmonious results in the working together of all parts of the institution. With much improvement still to be expected in things that are essential to the higher attainments which constitute the ultimate purpose, there is already the realization of even more than was foreseen in the beneficent influences that are here being revealed.

The report is illustrated by several excellent photographs of the new McLean buildings at Waverley.

MEDICAL NOTES.

BALTIMORE EYE, EAR AND THROAT HOSPITAL.—The directors of the Baltimore Eye, Ear and Throat Hospital intend to tear down the present building used by the hospital, and erect a new and handsome structure.

ANTITOXIN IN LONDON.—The report of the Medical Superintendent to the London Metropolitan Asylums Board on the use of antitoxin and the treatment of diphtheria during the year 1896 confirms the favorable results reached the previous year, the percentage of mortality being reduced from 29.6 in 1894 to 20.8 in 1896.

THE JUBILEE NUMBER OF THE "PRACTITIONER."—The *Practitioner* for June appears as a handsomely illustrated Jubilee Number, in commemoration of Queen Victoria's Diamond Jubilee, the whole number being devoted to an account of the advances which have been made in medicine, surgery and the allied sciences during the sixty years of her reign.

BOSTON AND NEW ENGLAND.

TRUSTEES OF INSTITUTIONS APPOINTED.—The Mayor of Boston has announced his appointments of trustees of the newly created Pauper Institutions Department, Children's Institutions Department and Insane Hospital Department, under the provisions of Chapter 395 and Chapter 451 of the Acts of the cur-

rent year, which have just gone into effect. Under the provisions of these acts each of these boards of trustees consists of seven members, two of whom must be women; and of the appointments first made on each board one is for the term of five years, two for the term of four years, one for the term of three years, two for the term of two years and one for the term of one year, all of such terms dating from the 1st day of May of the present year. While the law only requires the appointment of two women on each board, the mayor deemed it advisable to appoint three women as trustees of the Pauper Institutions Department and three as trustees for children. Of the twenty-one trustees appointed eight are women. Of the thirteen men, six are in business, four are physicians, one is a lawyer, one is a professor, one is a builder. Most of these appointments are excellent; all seem to be unobjectionable; and all the appointees seem to have had more or less interest or experience in the affairs which are to be under their charge.

THE BOSTON CITY HOSPITAL.—The action of the Boston Board of Aldermen in ignoring the appropriation asked for by the Board of Trustees, for much-needed improvements, is greatly to be regretted. Great improvements have been recently made in the hospital, and it has been brought to a very high state of efficiency. The present request for an appropriation of \$74,129 is based on an economical estimate of the cost of certain changes which are absolutely needed in order to efficiently carry on the work of this great charity. Money is already on hand for the construction of a suitable laundry building; but it is extremely difficult to see what advantage there is in a laundry building without proper heating apparatus, which is one of the items asked for by the trustees. The requirements of modern aseptic surgical work demand very extensive laundry facilities, and without them such work cannot be performed. The gynecological wards and operating-room also are in pressing need of improvement in order to be brought to a proper standard of efficiency. The electric-lighting plant is also defective, and the necessity for properly lighting a hospital is not difficult to see. The care of the sick poor is a duty which should be one of the first to appeal to those entrusted with the government of the city, and it is certainly to be hoped that the short-sighted policy of neglecting to attend to the very reasonable requests of a careful and economical board of trustees will not be persisted in.

A DINNER OF THE CLASS OF 1893, HARVARD MEDICAL SCHOOL.—The first dinner of the Harvard Medical School, Class of 1893, was held at Young's Hotel on June 8th, with thirty members present. Dr. J. W. Courtney, of Boston, was toastmaster. Drs. C. G. Page, J. E. Rourke, J. P. Treanor, of Boston, Dr. R. F. Cody, of New Bedford, Dr. W. M. Jones, of Lowell, and Dr. W. C. Boyd, of Linnaeus, Me., spoke. Dr. H. H. Haskell, of Boston, was chosen president. The Secretary, Dr. G. L. West, of Newton Centre, issued his first report, a pamphlet of over fifty pages.

EFFECTS OF THE ANNUAL DINNER OF THE MASSACHUSETTS MEDICAL SOCIETY. — A large number of cases of gastro-enteritis were reported among the members of the Massachusetts Medical Society following their annual dinner.

DR. ELY APPOINTED PROFESSOR AT YALE. — Dr. J. Slade Ely, of the College of Physicians and Surgeons of New York, has been appointed Professor of Theory and Practice of Medicine in Yale University.

NEW YORK.

COMMENCEMENT AT COLUMBIA UNIVERSITY. — The one hundred and forty-third annual commencement of Columbia University was held at the Carnegie Music Hall on June 9th. The degree of M.D. was conferred upon forty candidates, but there was no regular class of the medical department (the College of Physicians and Surgeons) graduated, owing to the new curriculum requiring a four years' course, introduced three years ago. At the next commencement the graduating class, the first to complete the course, will probably be an unusually large one. Among the winners of prizes announced were the following: the Cartwright prize of \$500 for the best medical essay, Dr. George W. Pride, Cleveland, O.; Stevens triennial prize of \$200 for the best medical essay, Dr. Erwin A. Tucker, New York; Joseph Mather Smith prize of \$100 for the best essay on a medical subject by an alumnus of the College of Physicians and Surgeons, Dr. Pearce Bailey, New York; Prize lectureship, valued at \$500 and tenable for three years, Dr. George J. Bayles, Philadelphia, Pa.

A DISAGREEMENT IN THE CONSOLIDATED MEDICAL SCHOOL. — An unfortunate disagreement has developed in the completion of the arrangements for the consolidation of Bellevue Hospital Medical College with the medical department of the University of the City of New York, owing, it is said, to the dissatisfaction of certain members of the faculties of the two schools with the distribution of the various professorships and lectureships announced a short time since. At a meeting of the Council of the University held June 10th, it was given out that a final decision in the matter would be made; but it is now stated that, after a long discussion, no decision was arrived at, and the question of the proposed consolidation was postponed until the next meeting. Prospects of union however, were rendered brighter by the conciliatory manner in which the opposing views were presented.

TWO NEW PROFESSORSHIPS AT COLUMBIA. — At a meeting of the Trustees of Columbia University held June 8th, two new professors in the medical department, Dr. James Ewen, in clinical microscopy, and Dr. A. Brayton Ball, in clinical medicine, were appointed. Among the gifts to the university acknowledged, was a bronze tablet, six by four feet, from the Sons of the Revolution, commemorating the battle of Harlem and the death of Lieutenant Knowlton on the site of the new buildings on Morningside Heights.

Miscellany.

AN ENGLISH ACCOUNT OF THE DISCOVERY OF ANESTHESIA.

DANIEL JOHN LEECH, M.D., F.R.C.P., in an article on "The Progress of Therapeutics during the Victorian Period" in the current number of *The Practitioner*, gives the following account of the discovery of anesthesia:

The anesthetic effects of nitrous oxide gas had been indicated by Davy at the beginning of the century, but it was first made use of by an American dentist named Wells in 1844, who himself took it and gave it for the purpose of extracting teeth without pain. It did not at this time come into general use, because, before its value could be established, two other substances, ether and chloroform, were introduced, which for most purposes had advantages over the gas.

Ether had been known for more than a century before its value as an anesthetic was recognized. As long ago as 1842 it had been administered by a medical man in the United States, W. C. Long, and a little later it was given for the extraction of teeth. It was not, however, until near the end of 1846 that there is a record of an operation performed on a patient under ether, and it was only after a communication made to the Academy of Sciences in January, 1847, that its effects as an anesthetic were generally known. Simpson adopted it to relieve the pains of childbirth in January, 1847; but in November of the same year he introduced a new anesthetic — chloroform — which had been discovered by Soubeyran in 1831. This had some advantages over ether, and its use rapidly spread, whilst that of ether was, in Great Britain at least, arrested for many years.

There certainly is, as he writes, "a record of an operation performed on a patient under ether" near the end of 1846, and it would seem only fair to mention the man who made the record and the place where it was made in an article of this sort.

Simpson's introduction of chloroform is hardly more important than that of ether. Dr. "W. C. Long," as every one knows, should read Dr. Crawford W. Long.

Obituary.

WILLIAM T. LUSK, M.D.

SELDOM has the profession and public received a severer shock than in the news of the sudden death of Dr. Lusk, in the full tide of his usefulness and the splendid zenith of his rare powers and extraordinary professional success. He died at his residence in New York on June 12th, of cerebral apoplexy.

William Thompson Lusk was born in Norwich, Conn., in 1839, and was a student of medicine when the late war broke out in 1861. Filled with patriotic ardor, he enlisted in a regiment of New York Volunteers, and within two years rose successively to the rank of lieutenant, captain and adjutant-general. In 1863 he left the army and resumed his studies, and in 1864 was graduated from Bellevue Hospital Medical College. From 1864 to 1868 he was engaged in professional study abroad, visiting Paris, Edinburgh, Vienna, Berlin, Heidelberg and other medical centres.

In 1872 he received the degree of M.A., and in 1893 that of LL.D., from Yale University. On his return from Europe he was for a time Lecturer on Physiology at Harvard, and afterwards accepted the Professorship of Physiology in the Long Island College Hospital, Brooklyn. In

1871 he was made Professor of Obstetrics and Gynecology in Bellevue Hospital Medical College; and seven years ago, on the death of Dr. Isaac E. Taylor, became President of the College.

At the time of his death he was a visiting gynecologist to Bellevue and St. Vincent's Hospitals, and consulting surgeon to the Maternity Hospital, the Skin and Cancer Hospital, and the New York Foundling Asylum. In 1889 he was elected President of the New York State Medical Association, and he was also at one time President of the American Gynecological Society and of the New York Obstetrical Society.

His contributions to the work of societies and to current medical literature were always of the highest order of excellence, and for several years he was editor of the *New York Medical Journal*. In 1881 he published his treatise on "The Science and Art of Midwifery," the extraordinary merits of which were promptly recognized by the profession. It at once took its position as a classic, quickly passed through a number of editions, and was early translated into French, Italian and Spanish. Dr. Lusk will perhaps be best remembered for his work in the prevention and treatment of puerperal fever.

As a teacher he had few equals, and as an obstetric and gynecological surgeon he achieved the most brilliant success. His results in Cæsarean section were especially noteworthy. While always in the forefront of scientific progress, he was eminently judicious and conservative in his methods and teachings; and he was among the first and most emphatic to protest against the almost indiscriminate practice of ovariectomy, which a few years ago threatened to bring widespread discredit upon the profession.

Though one of the most modest of men, he had a rare fascination of person and manner, and was deservedly among the most popular practitioners of the time. Notwithstanding the vast amount of work that he accomplished and the grave responsibilities continually resting upon him, he was always affable and considerate; and in his hours of relaxation no more genial and cheerful-hearted companion could be found. Gifted with an abounding vitality, he retained his youthful figure and appearance in the most remarkable degree, and scarcely any one would have guessed his age within ten or fifteen years.

With a career of such exceptional brilliancy, universally esteemed, respected and beloved, and fairly idolized by those who knew him intimately, the loss of such a man is indeed great.

Dr. Lusk was married twice and leaves two sons and three daughters. In memory of his first wife, her father, the Hon. S. V. Chittenden, of Brooklyn, erected a beautiful building at Yale University. Dr. Lusk's oldest son, Dr. Wm. Chittenden Lusk, although still very young, is Chief of the Surgical Clinic at Bellevue Medical School.

J. LEWIS SMITH, M.D.

DR. J. LEWIS SMITH, the eminent authority on pediatrics, died at his residence in New York on June 9th. For several years his health had been far from robust, and two or three months ago he received a severe shock in a runaway accident. Still, he was able to attend to his practice until within a short time of his death, when he met with another accident, on a cable car, which confined him to bed. His death was due to exhaustion and cardiac disease.

Dr. Smith was born at Spafford, Onondaga County, N. Y., October 15, 1827, and was graduated from Yale College in 1849. He studied medicine with the late Drs. Caleb Green and Frederick Hyde, of Cortland County, and attended lectures at the Buffalo Medical College in 1851 and 1852. He completed his medical studies in New York City, and was graduated from the College of Physicians and Surgeons in 1853.

From an early period in his professional career he de-

voted himself particularly to the study of the diseases of children, and in 1869 published his well-known treatise on that subject, which has passed through many editions and proved one of the most successful works ever written by an American medical author. In addition he was for many years a voluminous contributor to current medical literature, especially to such works as the "Annual of the Universal Medical Sciences"; and he wrote many articles on diseases of children in various encyclopedias and systems of medicine. What rendered his writing particularly valuable was his great industry and painstaking in making notes of the cases observed in his vast experience and his careful study of the pathological conditions presented by those proving fatal. He was, too, a diligent student of the advances made in the various departments of medical science, and was always among the first to put to a practical test any discovery which promised to add to the therapeutic resources of the profession.

For many years he was Professor of Diseases of Children in Bellevue Hospital Medical College; and he was also Attending Physician to Charity Hospital, the New York Foundling Asylum, and the New York Infant Asylum, and Consulting Physician to the Bellevue Bureau for the Relief of Out-door Poor, Department for Diseases of Children.

Dr. Smith was a brother of Dr. Stephen Smith, the well-known surgeon.

Correspondence.

TWELFTH INTERNATIONAL MEDICAL CONGRESS.

110 WEST THIRTY-FOURTH STREET,
NEW YORK, June 14, 1897.

MR. EDITOR:—The undersigned, Chairman of the American National Committee which was established at the request and under the authority of the General Committee of the Twelfth International Medical Congress, begs to inform the numerous gentlemen who are constantly applying for information concerning certificates, trips, fares, hotels, etc., that he has none to give, not having heard from the general committee these two months.

Very respectfully,

A. JACOBI, M.D.

CANCER OF THE BREAST IN A CHILD.

BOSTON, June 12, 1897.

MR. EDITOR:—Attention has been recently called to the occurrence of cancer of the breast in children, and several cases have been reported. I desire to place on record a case of this disease which has been for some time under my observation. The patient is a youth, who was born of healthy parents in whom no suspicion of malignant heredity can rest. The father has been at times grossly intemperate. Up to the age of twelve years this boy presented no appearance of glandular or other disease. Soon after this time a swelling was noticed in the left breast, beneath and attached to the nipple, which was slightly reddened and harder than its fellow: the swelling and induration gradually increased in size during the succeeding months, and the skin became more extensively adherent. At this time the lad was placed under my care, and after a short period of observation, an operation was advised, and performed. The growth, on microscopical examination, presented the typical structure of carcinoma, and had invaded all visible glandular tissue of the breast. The wound healed by first intention, and there has been no indication of recurrence or metastasis. The operation was performed five years ago.

Very respectfully,

ALBERT N. BLODGETT, M.D.

METEOROLOGICAL RECORD

For the week ending June 5th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—
